Fig. 2 shows the development of energy use in industries over time in the period 1990–2016 (based on IEA, 2018c). In this period an increase is visible of 56%, from 111 EJ to 174 EJ, mainly occurring in the 2000s. The share of iron and steel in this period increases from 15% to 19% and of chemicals from 22% to 26%. Also the non-metallic minerals sector shows an increase from 6% to 9%. Meanwhile the other sectors remain more or less constant, while the category “non-specified industries” (which is part of “others” in Fig. 2) decreases from 25% to 15%.

Fig. 3 shows the development of industrial energy use by country. Here it is quite visible that a large share of the increase in industries in the 2000s is related to growth in China. Excluding China, industries grow from 99 EJ in 1990 to 119 EJ in 2016 (increase of 20%). In China industries grow from 12 EJ to 55 EJ (+360%), increasing its share in global industrial energy demand from 11% in 1990 to 32% in 2016. Other fast growing countries are India (from 3.5 EJ to 10.8 EJ), South Korea (1.3–5.3 EJ), Saudi Arabia (0.8–3.2 EJ), Iran (1.0–3.2 EJ) and Brazil (2.3–4.0 EJ). The EU-28 is one of the regions with a decrease from 22 EJ in 1990 to 18 EJ in 2016. Also Russia (13 to 12 EJ), Japan (7.3 to 6.1 EJ) and the United States (20.3 to 19.7 EJ) show a decrease.

CO₂ emissions from energy use in industries (including oil refineries and non-energy use) amounted to 9.7 Gtonne CO₂ in 2016 (based on data from Fig. 1 and typical emission factors of 94 g CO₂/MJ for coal, 73 g CO₂/MJ for oil and 56 g CO₂/MJ for natural gas (IPCC, 2006)). Including indirect CO₂ emissions by electricity consumption adds 4.8 Gtonne CO₂ in 2016 (based on Fig. 1 and a global average emission intensity for power generation of 532 g CO₂/kWh in 2016 (based on IEA, 2018b)). Finally, industrial process emissions add another 3.2 Gtonne CO_{2eq} in 2014 (ClimateWatch, 2019). These emissions are for more than half related to process emissions from cement production, which were 1.7 Gtonne CO_{2eq} in 2012 (Janssens-Maenhout *et al.*, 2017). Together it means that total industry is responsible for about 35% of global GHG emissions, which were 50 Gtonne in 2014 (ClimateWatch, 2019).

Fig. 2 Global industrial energy use per sector. Based on data from IEA, 2018c. Extended World Energy Balances Database. 2018 ed. Paris: International Energy Agency (IEA).

Fig. 3 Energy use in industries by country. Based on data from IEA, 2018c. Extended World Energy Balances Database. 2018 ed. Paris: International Energy Agency (IEA).

Energy Efficiency Measures

In this section we will discuss main energy saving options in the main industrial sectors which are chemicals, iron and steel and cement. Also we include aluminum production, which is the biggest electricity consuming sector, after chemicals and iron and steel.

Chemicals

The chemical industry produces many different chemical products (e.g., ammonia, caustic soda and ethylene) and is by far the largest industrial energy user. The global energy demand of the chemical industry is 19 EJ excluding feedstock and 46 EJ including feedstock, accounting for about 26% of the total industrial energy demand in 2016 (IEA, 2018a). While the chemical industry produces thousands of chemicals, only a few chemicals consume most of the energy. These are the production of light olefins (ethylene and propylene), BTX aromatics (benzene, toluene and xylenes), ammonia and methanol, which account for 73% of the total energy use of the chemical industry (IEA, 2017). Improving the energy efficiency in the energy-intensive processes is key to reduce overall energy consumption in the chemical industry worldwide.

One of the main energy consuming processes is steam cracking of hydrocarbon feedstocks, which is used in the petrochemical industry to produce ethylene and propylene and BTX aromatics. These products are further processed into polymers, solvents and resins. Steam cracking results in a large variety of products with varying energy intensities and accounts for about 20% of the final energy use (excl. feedstocks and electricity in the chemical and petrochemical industry (IEA, 2009a)). Saygin *et al.* (2011) estimate that by implementing best practice technology the average world energy intensity of 16.9 GJ/tonne High Value Chemicals (HVCs) (including ethylene, propylene, benzene, butadiene, acetylene and hydrogen) could decrease by 26% (excl. feedstocks). When implementing best available technology an improvement of 37% was estimated to be possible (Kermeli *et al.*, 2014).

The manufacture of ammonia and methanol accounts for about 32% of the energy consumed in the chemical and petrochemical sector (IEA, 2017). Ammonia is mainly used as a feedstock in fertilizer production. Saygin *et al.* (2011) estimate a global fuel savings potential for ammonia production, when implementing best practice technology, of 31% (excl. feedstock and electricity use).

Methanol is used mainly as antifreeze, solvent and fuel. The majority of methanol production (80%) is natural gas-based with the remainder, mainly taking place in China, being coal-based (Kermeli *et al.*, 2014). The world average energy use in methanol production is estimated at 10.9 GJ/tonne (excl. feedstock and electricity) (Saygin *et al.*, 2011). The worldwide adoption of best practice technology (8.5 GJ/tonne), would result in a 22% decrease of the energy intensity.

Chlorine production is the main electricity consuming process in the chemical industry (Graus *et al.*, 2011). The most efficient production process for chlorine production is the membrane process which consumes 2600 kWh/tonne chlorine, which is already close to the most efficient technology considered feasible (IEA, 2008). As a comparison to commonly used mercury process has an energy intensity of around 4000–4500 kWh/tonne chlorine (Kermeli *et al.*, 2014), but is being phased out in many countries.

Table 1 gives an overview of the main energy efficiency technologies that can be implemented in the chemical industry with their main characteristics.

Table 1 List of energy efficiency technologies applied in the chemical industry

<i>Sector</i>	<i>Energy efficiency technology</i>	<i>Investment (€/tonne chemical)</i>	<i>Energy savings (%)</i>	<i>Source</i>
Ammonia	Adiabatic pre-reformer	17.7	7.5	Boulamanti and Moya Rivera (2017) and Kermeli <i>et al.</i> (2017)
	Heat exchange autothermal reforming	25.2	6	Boulamanti and Moya Rivera (2017) and Kermeli <i>et al.</i> (2017)
	Advanced conventional processes	31.5	10	Boulamanti and Moya Rivera (2017) and Kermeli <i>et al.</i> (2017)
	Reduced primary reforming and increased process air	29.4	5	Boulamanti and Moya Rivera (2017)
	Preheat mixed feed and efficient gas turbine	14.5	16.6	Boulamanti and Moya Rivera (2017)
	Advanced process control	6	2.3	Boulamanti and Moya Rivera (2017), Kermeli <i>et al.</i> (2017) and Yue <i>et al.</i> (2018)
	Low pressure ammonia synthesis catalysts		3.9	Boulamanti and Moya Rivera (2017) and Kermeli <i>et al.</i> (2017)
	Using hydrogen from water electrolysis	176	66.3	Boulamanti and Moya Rivera (2017)
	Improved the reforming section	37	13.3	Boulamanti and Moya Rivera (2017)
	Multi-nozzle opposed coal water slurry gasification	110	15	Yue <i>et al.</i> (2018)
	New reforming membranes ^a	348.1	17	Boulamanti and Moya Rivera (2017)
	Solid state ammonia synthesis ^a	241.1	66.3	Boulamanti and Moya Rivera (2017)
	Short contact time catalytic partial oxidation ^a	1670	11	Boulamanti and Moya Rivera (2017)
	Used new membranes for CO ₂ removal ^a		<5	Boulamanti and Moya Rivera (2017)
Light olefins	Decoking activities		<5	Boulamanti and Moya Rivera (2017)
	Advanced furnace materials such as selective radiant coils and ceramic-coated tubes	2.1	10	Boulamanti and Moya Rivera (2017)
	Improving compression and separation section (ICSS) – Advanced distillation columns	0.8	1.5	Boulamanti and Moya Rivera (2017)
	ICSS – Mechanical vapor recompression	0.6	5	Boulamanti and Moya Rivera (2017)
	Adsorption heat pump ^a	10.8	12	Boulamanti and Moya Rivera (2017)
	ICSS – Membranes ^a	18.4	8	Boulamanti and Moya Rivera (2017)
	Olefin production via methanol ^a		5	Boulamanti and Moya Rivera (2017)
	Energy integration – reformat based process	9.5	25 electricity and 20 thermal	Boulamanti and Moya Rivera (2017)
	Energy integration – pygas based process	9.5	9 thermal	Boulamanti and Moya Rivera (2017)
Hydrogen and methanol	Air preheat	6.8	5	Boulamanti and Moya Rivera (2017)
	Minimal steam: carbon ratio and associated measures		<5	Boulamanti and Moya Rivera (2017)
	Hydrogen from electrolysis	2211.7	35	Boulamanti and Moya Rivera (2017)
	Membrane methane reforming ^a	1978.0	20	Boulamanti and Moya Rivera (2017)
	Short contact time catalytic partial oxidation ^a	695.3	15	Boulamanti and Moya Rivera (2017)
Soda ash	Integrated design and operation	40	44.6 electricity and 17.6 thermal	Boulamanti and Moya Rivera (2017)
	Vertical shaft kiln for the production of concentrated CO ₂ gas and reactive lime	16	2.7	Boulamanti and Moya Rivera (2017)
Chlor-alkali	Conversion of mercury to membrane cell plants	426.2	28.4 electricity	Boulamanti and Moya Rivera (2017)
	Conversion of asbestos diaphragm to membrane cell plants	367	7 electricity and 70.5 steam	Boulamanti and Moya Rivera (2017)
	Asbestos-free diaphragms	10	4.4 electricity	Boulamanti and Moya Rivera (2017)
	High performance bipolar membrane cells	21	13.6 electricity	Boulamanti and Moya Rivera (2017) and Yue <i>et al.</i> (2018)
	High performance electrodes and coatings		3–4	Boulamanti and Moya Rivera (2017)
	Recovered hydrogen as a chemical reagent or fuel		<5	Boulamanti and Moya Rivera (2017)
	Oxygen depolarized cathodes ^a	89	15	Boulamanti and Moya Rivera (2017) and Yue <i>et al.</i> (2018)
	Four-stage caustic evaporator in membrane plants ^a		20	Boulamanti and Moya Rivera (2017)

Table 1 Continued

<i>Sector</i>	<i>Energy efficiency technology</i>	<i>Investment (€/tonne chemical)</i>	<i>Energy savings (%)</i>	<i>Source</i>
Ethylene oxide & ethylene glycols PVC	Shell OMEGA process	244.4	20	Boulamanti and Moya Rivera (2017)
	Pigging system	101,568 (for 100 m pipeline)	19 electricity	Boulamanti and Moya Rivera (2017)

	Automatic control system for materials feeding and batching	12	4 electricity	Yue <i>et al.</i> (2018)
	Waste heat of flue gas for power generation	33	11 electricity	Yue <i>et al.</i> (2018)

^aUncommercialized technology.^bThe technologies used in calcium carbide are mainly based on China because China represents around 95% of global production and consumption of calcium carbide (SEC: 3400 kWh/t-calcium carbide).

Energy efficiency improvement through the use of best practice technologies can reach around 17% for the chemical industry. Higher potentials can be realized through process integration (4%), Combined Heat and Power (CHP) generation (10%) and recycling and energy recovery (1%) (Saygin *et al.*, 2011). From the regional perspective, IEA indicate that China has the largest potential to improve energy efficiency in the chemical industry, accounting for 40% of global energy savings potential (IEA, 2013).

At the end of the useful life of plastics, it is possible to save energy by recycling (mechanically or as feedstock) and energy recovery. Mechanical recycling is by far the most widely used approach worldwide. The main alternatives to recycling are incineration (with and without energy recovery) and landfilling. Globally, less than 10% of the total plastic waste is recycled. In Europe and Japan, the share of recovered plastic waste (by mechanical recycling and energy recovery) is higher than global average. Around 20% of the plastic waste is mechanically recycled and 30% is combusted with energy recovery in Europe. The remaining 50% is unrecovered (disposed by landfilling or incinerated without energy recovery). In Japan the share of recovered waste is higher than in Europe (60% in comparison to 50%) (Saygin *et al.*, 2011).

As seen in Section "Energy Use and Greenhouse Gas Emissions in Industries", China is one of the main energy consuming countries in terms of industrial energy use, being responsible for 32% in 2016. This is reflected in China's chemical industry which shows a strong growth since 2000, with an annual growth rate of 9%, for main chemicals (Yue *et al.*, 2018). As the largest chemical market worldwide, China represents around 1/3 of the global chemicals production. In particular, China is the largest producer and consumer of ammonia, caustic soda, polyvinyl chloride and calcium carbide. Energy consumption of China's chemical industry increased with the growth of chemicals output from 4.1 EJ in 2000 to 14.4 EJ in 2015, accounting for 11% of China's total energy demand. The final energy consumption mix of China's chemical industry shows that electricity has increasingly become the dominant energy source, amounting to 30% in 2015. The growing energy consumption of the chemical industry has resulted in enormous emissions of air pollutants and GHGs. Energy-related CO₂ emissions of China's chemical industry account for 3.7% of global total in 2015, with 1220 Mt CO₂, which nearly doubled since 2005. As a key emitter of air pollutants, China's chemical industry emitted 2254 kt of SO₂, 1512 kt of NO_x and 808 kt of PM in 2015, contributing 12%, 8%, and 5% to the national emissions, respectively (Yue *et al.*, 2018).

Cement

In 2014, the cement industry consumed 10.6 EJ of energy (7% of industrial energy use). Due to the high level of process emissions, cement production comprises the second largest industrial emitter, following the iron and steel industry, accounting for 27% (2.2 GtCO₂ in 2014) of industrial emissions and 6% of global CO₂ emissions (IEA, 2017).

Main processes in cement manufacturing are raw material preparation, clinker production (limestone calcination) and cement grinding; with clinker production being the most energy intensive step (Worrell and Galitsky, 2008). Clinker is produced by burning a mixture of mainly limestone, silicon oxides, aluminum oxides and iron oxides in a kiln. Based on the moisture content of raw materials, clinker production can take place in a wet, dry, semi-dry or semi-wet kiln. The dry process has lower energy requirements due to lower evaporation needs.

The adoption of more energy efficient technologies and the decrease of the clinker content in cement can significantly reduce the energy use in cement manufacturing.

The thermal energy use for clinker production in the different world regions ranges between 3.1 and 5.0 GJ/tonne clinker (see Fig. 4). It differs mainly due to the kiln technology type used and the level of energy efficiency (Kermeli *et al.*, 2019). The lowest energy consumption is observed in India where cement capacity increased significantly in recent years. The highest is in CIS which still relies heavily on the wet process. Dry kilns equipped with a precalciner and several preheater stages (5–6 stages), are currently considered best available technology, and can have under optimal conditions a fuel consumption of about 2.9–3.3 GJ/tonne clinker (EIPPCB, 2010). The theoretical minimum energy requirements are about 1.65–1.8 GJ/tonne (WBCSD/CSI-ECRA, 2009). The difference in energy use between typical kilns and the theoretical energy occurs mainly due to heat losses. The energy use in state-of-the-art dry kilns is not expected to significantly decrease in the future (IEA, 2009a).

In the cement industry, electricity is mainly used for the preparation of raw materials, fuels and additives, and for cement grinding. Current state-of-the-art techniques use roller presses and vertical roller mills for grinding. The energy requirements mainly depend on raw material hardness, moisture content and the type and amount of additives used. Fig. 5 shows the electricity use for cement making in different world regions. In 2012, electricity use ranged between 81 and 126 kWh/tonne cement. The lowest electricity use is observed in India and the highest in the North America and CIS. The implementation of best practice technology can decrease electricity use to about 70 kWh/tonne cement.

Table 2 shows main energy efficiency measures for clinker making for dry process cement plants, including fuel savings, electricity savings and payback period.

Additional energy savings can be obtained by reducing the clinker content in cement. Portland cement has a clinker to cement ratio of 95%–100% (the remaining part is gypsum). Substituting a part of clinker with other materials with similar properties (hydraulic and/or pozzolanic) reduces the clinker content in cement lowering the demand for clinker. Reducing clinker production by 1 tonne will roughly reduce CO₂ emissions by the same amount. Cements that contain clinker substituting materials in considerable quantities are known as blended cements. These materials are either interground with clinker in the final step of cement making or are ground and dried separately before being mixed with clinker. Clinker can be substituted by industrial by-products such as coal fly ash, blast furnace slag or pozzolanic materials (e.g., volcanic material). The relative importance of additive use can be expressed by the clinker to cement ratio. Fig. 6 shows the clinker content in cement for different world region. The average clinker to cement ratio is estimated at 70% (Kermeli *et al.*, 2014).

Iron and Steel

Steel is a widely used material in modern society, which has been linked to the development of steel end use sectors, e.g., building and infrastructure, manufacturing, and transport systems. The iron and steel industry is one of the world's

Fig. 4 Heat consumption for clinker making per world region (excluding heat loss for drying). Reproduced from Kermeli, K., Edelenbosch, O.Y., Crijns-Graus, W., *et al.*, 2019. The Scope for Better Industry Representation in Long-Term Energy Models: Modeling the Cement Industry.

Table 2 Energy efficiency measures for clinker making – dry process plants

Energy efficiency measure	Specific fuel savings (GJ/tonne clinker) ^a	Specific electricity savings (kWh/tonne clinker) ^a	Estimated payback period (years) ^b
Energy management and control systems	0.1–0.2	0–4.9	<2
Kiln combustion system improvements	0.1–0.4	–	1.0–5.0
Mineralized clinker	0.0–0.2	0 to –1.0	N/A
Indirect firing	0.2	0 to –0.6	>10
Oxygen enrichment	0.0–0.2	(–)9 to (–)32	N/A
Mixing air technology (PH kilns)	0.20	(–) 0.03	2
Seal replacement	0.02	–	<1
Kiln shell heat loss reduction	0.1–0.6	–	<1
Preheater shell heat loss reduction	0.02	–	6
Refractories	0.06	–	4
Conversion to grate cooler	0.3	(–)3.00 to (–)6.00	>18
Optimize grate cooler	0.05–0.16	0.0 to (–)2.0	2.00–7.00
Low-pressure drop Suspension preheaters	–	0.6–4.4	>10
Heat recovery for power generation	–	20.0	2.00–14.00
Conversion of long dry to preheater	0.7–1.6	–	10
Increase preheater stages (from 5 to 6)	0.1	–	>7
Addition of precalciner or upgrade	0.2–0.7	–	>10
Conversion of long dry kiln to preheater precalciner	0.84–1.11	–	>10

^aNegative values for electricity saving indicate that although the application of this measure saves fuel, it will increase electricity consumption. However, the total primary energy savings of these measures is positive.

^bThe estimated energy and expenditure savings and payback periods are averages for indication, based on the average performance of the U.S. cement industry (e.g., clinker to cement ratio). The actual savings and payback period may vary by project based on the specific conditions in the individual plant.

Note: Worrell, E., Kermeli, K., Galitsky, C., 2013. Energy Efficiency Improvement and Cost Saving Opportunities for Cement Making. United States Environmental Protection Agency (U.S. EPA).

largest energy consumer and therefore a major contributor to global anthropogenic CO₂ emissions, accounting for 9% of global energy use and 4%–7% global anthropogenic CO₂ emissions (Pauliuk *et al.*, 2013). In the period 1960–2018, the historical steel production has risen fivefold. In 2018, China is the largest steel producer, accounting for 51.3% of the global total, followed by the European Union, India, USA, and Japan (World Steel Association, 2019). Many studies indicate that global steel demand is expected to more than double by 2050, depending on the industrialization in developing regions (Ruijven *et al.*, 2016).

Manufacturing steel can be divided into the following processes; raw material preparation (including coke making, iron ore extraction and sinter/pellets making), iron making, steel making, casting, rolling, forming and coating, and fabrication. Currently, two manufacturing routes have been widely used in crude steel production. The integrated route is based on iron ore and

Fig. 6 Clinker content in cement in the different world regions. Reproduced from Kermeli, K., Edelenbosch, O.Y., Crijns-Graus, W., *et al.*, 2019. The Scope for Better Industry Representation in Long-Term Energy Models: Modeling the Cement Industry.

limestone and consists of coke ovens, sinter/pellets plants, blast furnaces (BF) and Basic Oxygen Furnaces (BOF) or an open-hearth furnace (OHF), while the recycling route uses scrap as main material in electric arc furnaces. For integrated steel-making, around 70% of energy is consumed in the blast furnaces, followed by sintering and coke making (Zhang *et al.*, 2014). For the recycling route, scrap is mainly coming from casting, forming and other fabrication processes in steel making and after use (Cullen *et al.*, 2012). The energy consumed in the recycling route is about 20% of the energy used for integrated steel making from iron ore, because using scrap offsets the demand for energy and natural resources in the iron making process (Kermeli *et al.*, 2014). In 2016, 74% of global crude steel production was produced by the integrated route while 25.5% came from electric arc furnaces. There are two relatively new manufacturing routes, namely direct-reduced iron (DRI) and smelting reduction, which currently together account for less than 1% of global steel production. The key advantage of these routes is that 20%–25% of CO₂ can be avoided, compared to the integrated route (Pardo *et al.*, 2012).

Specific energy consumption and the associated CO₂ emissions per ton of steel production differ widely across countries, due to the difference of production route applied, plant size, level of waste heat recovery, quality of iron ore, and operation efficiency of the plants (IEA, 2012b; Worrell and Carreon, 2017). Since 1960, the energy intensity in the global iron and steel industry improved significantly and decreased by 60%. There are still large opportunities to improve energy efficiency though. Overall, the implementation of best available technology (BAT) could save 9%–18% of energy use (Worrell and Carreon, 2017). Table 3 lists the current best available technologies for energy-efficiency improvement in the iron and steel industry. The energy savings potential varies per country. Take China as an example, cogeneration by heat recovery, coke dry quenching (CDQ) and coal moisture control (CMC), injection of pulverized coal in BF are the most important measures to save energy and together can reduce energy use by 50% in the integrated steel making route. For the recycling route, scrap preheating and process control could contribute to one third of energy saving (Zhang *et al.*, 2014). Milford *et al.* (2013) estimate that energy efficiency alone is not enough to limit CO₂ emissions in the iron and steel sector, which would only decrease up to 20% of emissions by 2050, compared to a business-as-usual scenario. Therefore, material efficiency improvement is another key opportunity to reduce energy use and consequently lower CO₂ emissions. Strategies to improve material efficiency include reducing demand for the service, optimizing the weight of products, reducing yield losses, increasing product lifespans and recycling of end-of-life scrap (Allwood *et al.*, 2013). With the growing concern for climate change and ambitions to lower global temperature increase to well below 2°C, deeper decarbonization of the steel industry is needed, e.g., by using Hydrogen (H₂) or electricity to replace coke in the blast furnaces or the adoption of carbon capture and storage (CCS) and carbon capture and usage (CCU).

Aluminum

The primary aluminum industry is one of the top electricity consuming industries and is responsible for about 8% of global electricity consumption in industries (Kermeli *et al.*, 2014). The production of primary aluminum is a multi-stage process. Initially, bauxite ore is resolved/digested and refined into alumina in the Bayer process. Alumina is then transformed into aluminum in an electrolytic cell with the Hall-Héroult process. Molten aluminum is cast into ingots which are transferred and further processed in aluminum foundries. The most energy intensive processes in primary aluminum production are alumina refining and aluminum smelting, responsible for 27% and 70% of energy use, respectively. Anode production is responsible for about 2%, while aluminum casting for about 1.4% of the energy use (IAI, 2013a).

Table 3 Main energy efficiency measures

Process	Measures	Fuel saving (GJ/ton)	Electricity saving (GJ/ton) ^a	Capital cost (2005 \$/ton)
Sintering	Small pellet sintering technology	0.26	0.00	2.06
	Low temperature sintering	0.26	0.00	2.95
	Improved charging method	0.10	0.00	1.07
	Increasing bed depth	0.10	0.00	0.00
	Heat recovery from sinter cooler	0.40	0.00	2.93
Coke making	Use of waste fuel in sinter plant	0.16	0.00	0.21
	Pressure Shift-Absorbing Technique in H ₂ unit	0.05	0.00	0.00
	Programmed heating in coke oven	0.16	0.00	0.21

^aNegative values for electricity saving indicates that although the application of this measure saves fuel, it will increase electricity consumption. However, the total primary energy savings of these measures is positive.

China Science and Technology Press.

The typical energy use for alumina refining with the Bayer process is 12 GJ/tonne (Henrickson, 2010). China and Russia due to their poor quality bauxite reserves have used alternative processes to produce alumina; the Combined Bayer-Sinter and the Sinter processes with typical energy consumptions of 26 and 38 GJ/tonne alumina, respectively (Li *et al.*, 2008; Smith, 2008). Other processes that have been only recently widely used in China are the Flotation-Bayer and the Lime-Bayer processes (Gu and Wu, 2012). If China and Russia would use good quality bauxite and adopt the more energy efficient Bayer process, the energy consumption would significantly decrease. In 2009, the world average energy use for alumina refining, excluding China, is estimated at 12.5 GJ/tonne alumina. Energy efficient alumina refineries (Bayer process) can have an energy use of 8–11 GJ/tonne (Wischnewski *et al.*, 2011; Worrell *et al.* 2008; Henrickson, 2010) while the theoretical minimum energy requirement is 0.24 GJ/tonne (BCS, 2007).

As mentioned, the production of primary aluminum from alumina (aluminum smelting) is the most energy intensive step in primary aluminum production. Aluminum is produced by passing a direct current through a bath with alumina dissolved in a molten cryolite electrode. The electricity intensity in the various world regions ranged between 13.5 and 15.6 MWh/tonne aluminum in 2014 (IEA, 2017). The theoretical minimum energy requirement for electrolysis is 6.0 MWh/tonne (IEA, 2009a) while best practice is 13.5 MWh per tonne (IEA, 2017).

The primary aluminum industry is a large energy consumer and also a major greenhouse gas (GHG) emitter, as next to the emitted greenhouse gas emissions during fuel combustion and electricity generation, perfluorocarbons (PFCs) are emitted. PFCs are gases with a high global warming potential (GWP), ranging from 6500 times for tetrafluoromethane (C_2F_4) and 9200 times for hexafluoromethane (C_2F_6) the GWP of carbon dioxide (CO_2) (IPCC, 2006). In 2007, the primary aluminum industry emitted a total of about 400 Mt CO_2 -equivalent of GHGs (including indirect CO_2 emissions from electricity consumption and process emissions from aluminum smelting); equivalent to about 1% of global greenhouse gas emissions (IEA, 2009b). In the same year, IAI estimates global PFC emissions from aluminum smelting at about 29 Mt CO_2 -eq (IAI, 2013b).

Tables 4 and 5 show main measures for energy efficiency improvement for alumina refining and smelting, respectively. Besides these measures cogeneration of heat and power can be implemented in alumina refineries which could lead to 15% energy savings (Moya Rivera *et al.*, 2015). Furthermore waste energy from smelter off gases could be recovered (3–5 GJ/tonne aluminum accessible heat) (Moya Rivera *et al.*, 2015). The adoption of this technology depends on the proximity of heat demand in the surroundings of the smelter. Few currently available technologies can reduce the energy use in aluminum smelters. Innovative technologies such as wetted cathodes and inert anodes, although promising, are still being developed.

Aluminum can also be produced from scrap, in the secondary production route. Only 5% of the energy needed to produce primary aluminum is required to produce aluminum from scrap (IEA, 2012a). Around 30.5 Mtonnes of aluminum scrap was used in 2017 globally, which contributed to around 32% of aluminum production (World Aluminum, 2019). Out of the total scrap, 12.5 Mtonne consists of new scrap (e.g., from casting) and 18 Mtonne is from end-of life scrap. Total end-of-life scrap is estimate to be 25 Mtonne, implying that absolute scrap use can be increased up to 23% by higher recycling rates, thereby increasing the share of scrap used up to 39%. Aluminum products can be recycled repeatedly; cans, aluminum foil, and automotive components can be melted down to make

Table 4 Energy efficiency improvements for alumina refining

Measures	Electricity savings (kWh/tonne alumina)	Fuel savings (GJ/tonne alumina)	Investment costs (\$/tonne alumina)
Sweetening	N/A	0.9	8
Tube digestion + indirect heating	–	4.4	36–97
High rate thickeners – HT Plants	N/A	0.2	6
High rate thickeners – LT Plants	N/A	0.15	6

Table 5 Energy efficiency improvements for aluminum smelting, anode production and ingot casting

<i>Measures</i>	<i>Electricity savings (MWh/tonne aluminum)</i>	<i>Fuel savings (GJ/tonne aluminum)</i>	<i>Investment cost (\$/tonne aluminum)</i>
VSS → Point fed pre baked	2.8	–	2600
HSS → Point fed pre baked	2.8	–	2600
SWPB → Point fed pre baked	0.8	–	620
CWPB → Point fed pre baked	1.7	–	260
Optimize cell operation	2.0	–	240–410
Optimum combustion air flow	–	0.2–0.8	2.2–3.0
Efficient operation of burners	–	0.2–0.3	1.6–2.0
Furnace pressure control	–	0.2–0.3	1.4–1.8
Furnace insulation	–	0.1–0.2	0.4–0.6
Waste heat recovery	–	0.3–1.0	8–12
Sensor and control systems	–	0.2–0.3	0.2–1.0
Optimized motor system operation	0.1	–	7

Note: Kermeli, K., Ter Weer, P.H., Crijns-Graus, W., Worrell, E., 2015. Energy efficiency improvement and GHG abatement in the global production of primary aluminium. *Energy Efficiency* 8 (4), 629–666.

again similar products. The share of secondary aluminum production cannot be increased infinitely, as product quality is affected by the use of scrap as a feedstock. Certain high quality products will still require the use of new aluminum.

Conclusions

The industrial sector is a major energy consumer, responsible for 36% of the global final energy consumption and about 35% of global greenhouse gas emissions. Main energy consuming sectors are chemicals, iron and steel and cement.

The implementation of best available technologies can lead to reduced energy use and greenhouse gas emissions. Energy savings depend on the current level of efficiency, sector and production characteristics, but are typically in the range of 20%–40%.

In the coming twenty years industrial energy use is expected to increase by about 40%. This means that in light of 2° scenarios, besides energy-efficiency measures, other measures are needed to reduce greenhouse gas emissions. Crucial in this regard is material efficiency in a broad sense, including limiting material use by product design, re-use of materials, recycling of materials and substitution of materials. For longer term and further greenhouse gas emission reduction, measures such as carbon capture and storage are needed or fossil fuel substitution by hydrogen or electricity (produced from renewable energy) and biomass.

Introduction

The term *manufacture* originated from two Latin words: *Manus* ("hand") and *factus* ("make"). The Oxford English Dictionary defines *manufacture* as "to make or produce goods in large quantities, using machinery." In other words manufacturing means to create and add value to the product. This can also be understood as the conversion of materials input into goods and services (Ford and Despeisse, 2016). The various sustainability issues in manufacturing are energy consumption, waste generation, water usage, and the environmental impacts during the production phase and also for manufactured parts in service (Sreenivasan *et al.*, 2010). Moreover, cleaner production and environmental sustainability are necessary to prevent the depletion of environmental resources during manufacturing (Le Bourhis *et al.*, 2014).

The article begins with an overview of manufacturing processes (Fig. 1), followed by a review of previous studies on environmental issues of subtractive and additive manufacturing processes. The primary cause of industrial hazards is the fundamental workings of conventional additive manufacturing processes (such as welding, casting, forging, and heat treatment), which involve heating of metal to high temperature to join or reshape the material for the production of the desired goods. Subtractive manufacturing techniques also contribute to environmental pollution and various sources will be discussed in later section. This article also explores examples from current practice.

Additive Manufacturing Processes

As the name signifies, additive manufacturing means addition of material during the part building process. It includes various joining (assembly) processes and rapid prototyping processes (regenerative processes). Further, assembly processes encapsulate welding and fastening. The most significant risks of welding and microwelding operations in industry are the environmental hazards produced, knowingly or unknowingly. This releases heavy metal particles and metal oxides into ambient air, which increases environmental pollution. As the basic principle is the application of heat and pressure to join two metals, the heating process tends to melt the metal for short duration at specified locations. This leads to release of toxic gases and metal fumes of variable composition, which depends upon base metal or alloy and material welding. During complex vaporization, condensation, and oxidation processes, various hazardous gases such as carbon dioxide, carbon monoxide, nitrogen oxides, sulfur dioxide, and ozone are released into the environment. Moreover, it is estimated that about 90%–95% of metal fumes are produced from heating of filler metal and flux coating of filler metal. These metal fumes consist of various components in gaseous and solid state at the macro, micro, and nanoscale.

It is estimated that about five tonnes of fumes are emitted by the welding industry annually if an average 0.5% of metals are released in air during metal joining process. In spite of automation, 3 million people are presently involved directly or indirectly in this profession, who are knowingly or unknowingly subjected to these environmental hazards.

The testing of samples collected from tin–lead microwelding site revealed fast evolution of nanoparticles (5.6–560 nm), which is representative of nucleation mode as demonstrated by Avino *et al.* (2015). Moreover, they found that pollution caused by copper–aluminum soldering was 20 times higher than tin–lead micro welding.

Fig. 1 Classification of manufacturing process.

Table 1 Concentration of particulate matter in welding industries

Industry type	Particle concentration ($\mu\text{g}/\text{m}^3$)			
	Outdoor PM_{10}	Indoor PM_{10}	Outdoor PM_5	Indoor PM_5
Small A	474.1 $\pm$ 71.3	540.9 $\pm$ 69.1	5.82 $\pm$ 2.76	9.13 $\pm$ 3.40
Small B	448.8 $\pm$ 120.4	520.2 $\pm$ 63.3	8.11 $\pm$ 4.19	13.44 $\pm$ 4.26
Medium A	523.7 $\pm$ 31.7	581.0 $\pm$ 41	12.20 $\pm$ 4.03	21.64 $\pm$ 9.05
Medium B	580.9 $\pm$ 54	578.1 $\pm$ 45	16.04 $\pm$ 5.01	30.30 $\pm$ 6.37
Large	650.7 $\pm$ 69.6	679.0 $\pm$ 59.5	23.13 $\pm$ 9.40	38.60 $\pm$ 12.70

Note: Pervez, S., Mathew, J., Sharma, R., 2005. Investigation of personal-indoor-outdoor particulate relationships in welding workshops. *Journal of Scientific and Industrial Research* 64, 454–458.

Table 2 Concentration of hazardous gases and total dust during welding operation

	Concentration of gases and metals (mg/m^3)								
	SO_2	CO	CO_2	Mn	P	Al	Ni	Ca	Cr
Metal cored wire	2.09	181	3590	16.86	–	1.809	0.1741	0.717	0.0785
Self-shielded wire	2.62	17.2	5760	2.574	2.376	8.564	0.0742	0.4356	0.00495

Note: Popović, O., Prokić-Cvetković, R., Burzić, M., Lukić, U., Beljić, B., 2014. Fume and gas emission during arc welding: Hazards and recommendation. *Renewable and Sustainable Energy Reviews* 37, 509–516.

Similarly, [Pervez et al. \(2005\)](#) collected data from small, medium, and large scale Indian industries, which extensively performed welding operations to investigate adverse effects on environmental air. The concentration of particulate matter less than $10\text{ }\mu\text{m}$ (PM_{10}) and five micron (PM_5) was found beyond permissible limits as per Indian standards. Moreover, it was found that PM_{10} concentration was 1.5 times and PM_5 was 2 times greater in indoor as compared with outdoor locations ([Table 1](#)).

[Popović et al. \(2014\)](#) measured concentration of various gases and metal fumes involved in ambient air at indoor conditions using metal cored and self-shielded wire during arc welding operation ([Table 2](#)). It was found that the quantity of few harmful gases and toxic metal fumes was higher than permissible limits, which must be controlled to prevent environmental hazards.

In steel and iron manufacturing industries, many pollutants are involved during various stages of metal processing. During different metallurgical processes performed on iron ores, poisonous gases such as carbon monoxide, sulfur dioxide, and other heavy metals such as manganese, lead, nickel, arsenic, cadmium, and chromium are released in ambient air, which deteriorates the overall air quality.

In foundry industries, the major pollutants are released during pattern making, sand preparation, molding, mold drying, ladle heating, pouring and mold cooling, knockout, fettling, and heat treatment processes. Moreover, during pouring operations in the casting industry, the metal fumes, gases, vapors, and smoke are produced in excess amount.

In a comprehensive study on airborne particles emitted in cast iron foundries conducted by [Moroni et al. \(2014\)](#), the bulk chemical approach was used for characterization of aerosol samples; see [Table 3](#). The testing of air samples under scanning electron microscopy, transmission electron microscopy, and energy dispersive x-ray spectroscopy revealed excess amount of carcinogenic agents such as quartz and other heavy metals. The quartz was found above permissible limits at sand making and molding sites of industry. At shaking out locations, carbonaceous material consisting of irregular chains of carbon with size up to $1\text{ }\mu\text{m}$ was found. Moreover, concentration of heavy metals such as zinc, lead, manganese, and iron was found near the melting zone.

[Rafiei et al. \(2009\)](#) tested air quality on two production lines of the steel manufacturing industry in Iran and found higher levels of respirable particulate matter (3.09 and $3.78\text{ mg}/\text{m}^3$) in ambient air as compared with permissible limits ($3\text{ mg}/\text{m}^3$). Moreover, health tests showed that workers exposed to this environment were under higher risk of cardiovascular, pulmonary, and psychological diseases. Similarly, [Chohan and Bilga \(2011\)](#) found higher concentration of suspended particulate matter ($175\text{ }\mu\text{g}/\text{m}^3$) in small scale steel manufacturing industries in India. There was a significant impact of exposure conditions on workers' pulmonary functions as compared with control group workers who were unexposed.

In addition to casting, steel making, and welding operations, there are many other conventional manufacturing processes that significantly contribute to environmental pollution. For instance, heating of metals at higher temperature for heat treatment suspends micro-sized metal fumes in the air. In addition to this, various waste chemicals used in heat treatment result in water pollution in case of inadequate disposal facilities.

In addition to adverse effect on air quality, the excessive heat and noise released by conventional manufacturing units is a matter of grave concern. There are a plethora of production processes such as pressing, blanking, punching, molding, grinding, forging, fettling, trimming, and barreling creating both intermittent and impulsive noise. Prolonged exposure to loud noises (above 88 dB) may lead to cardiovascular disease, high stress, high blood pressure, and headache. The high-intensity noise may

Table 3 Mass concentration of samples at different locations in two foundries

Foundry	Location	Mass concentration (mg/m ³)
1	Melting	0.60
1	Molding	0.77
1	Sand making	2.72
1	Shakeout	0.70
1	Cleaning	1.22
1	Core making	0.28
2	Shakeout	0.74
2	Core making	0.18
2	Molding	0.48
2	Melting	0.60
2	Sand making	0.72

cause even permanent or temporary hearing loss/deafness and central nervous system disorders. Singh *et al.* (2010) found that noise levels in a foundry in India were than the permissible limits (90 dB). The noise levels at drop forging and grinding locations may increase up to 135 dB, which is highly hazardous for those workers who don't use personal protective equipment.

In the casting, forging, and steel making processes, the second most prominent environmental hazard is excessive heat evolved during various activities. The workers engaged in these tasks are more highly prone to heat stress, heavy sweating, and daily tiredness. Chohan and Bilga (2011) reported high heat concentration near steel furnace with dry bulb temperature more than 37°C whereas the permissible temperature level for working conditions recommended by OSHA is 27.80°C. Singh *et al.* (2010) measured wet bulb temperature at casting unit ranging from 32.17°C to 37.31°C and in forging unit ranging from 33.47°C to 38.03°C in an Indian working environment. In casting and forging industries, the major source of heat is induction and oil fired furnace and heat treatment.

Many developed nations have minimized the use of these aforementioned additive manufacturing techniques (welding and casting) owing to enormous environmental hazards. This led to a shift toward regenerative manufacturing processes commonly known as rapid prototyping or 3D printing. The distinction of rapid prototyping processes (such as selective laser melting, selective laser sintering, electron beam melting, fused deposition modeling, and stereolithography) is due to their good environmental characteristics (Sreenivasan *et al.*, 2010). By utilizing only the amount of material required for the product, rapid prototyping methods have the potential to limit the life cycle material mass and energy consumed as compared with subtractive manufacturing techniques. This can be achieved by eliminating scrap and the pollution enablers. Although it is costly, it can be considered as an innovative mode of part production (Kafara *et al.*, 2017). Le Bourhis *et al.* (2014) formulated a predictive model of consumption and integrated it into the design process, which evaluated the product's environmental impact during manufacturing. The model optimization can also be carried out by keeping environmental issues in view. However, environmental issues can also be compensated by enhancing the functionality of additive manufacturing manufactured parts (Kellens *et al.*, 2017).

Subtractive Manufacturing Processes

Subtractive manufacturing is basically a process of removing materials through chip formation using a sharp cutting tool by the application of mechanical energy using cutting fluid to maintain the temperature at the cutting zone. Some of the common subtractive manufacturing process are milling, turning, drilling, grinding, broaching, and sawing. Apart from these traditional manufacturing processes, a multitude of nonconventional processes have been developed over the last three decades to overcome the limitations of the former. These nontraditional subtractive manufacturing techniques have a tendency to machine a material with greater hardness and complex shapes with comparatively higher accuracy and lower cost. Interestingly, these advanced techniques have higher initial cost but they have played a major role in area of micromachining as a smaller amount of material is removed from the workpiece. Chemical machining, electrodischarge machining, and laser beam machining are some of the advanced subtractive techniques.

In subtractive manufacturing processes, a plethora of solid, liquid, and gaseous wastes can be identified, which have a significant impact on environment and occupational health (Fig. 2). Furthermore, noise and vibrations, fire and explosions, and other accident-related factors arising from these processes also pose grave danger to the environment.

Metal dust, in the form of fine particles with size ranging from submicrons to a few nanometers, is produced when material is particularly machined in dry conditions or inadequate lubricating conditions. Metal dust is also produced from friction between the cutting tool and work material, and rubbing of different machine components with each other. In the grinding process, for example, fine dust is produced from both the wheel and machined parts. As beryllium, silicon, chromium, zinc, nickel, and cobalt

Table 4 Machining liquids and chemicals used in advanced subtractive process

Sl. no.	Manufacturing process	Materials/liquids/chemicals used	Environmental threats
1	Chemical machining	FeCl ₃ , CuCl ₂ , and alkaline etchants	Hafnium suspended in air, disposed waste chemicals
2	Electrochemical machining	Sodium chloride, sodium nitrate	Hydrogen gas, mists, chromate, nitrate and ammonia suspended in air, disposed waste chemicals
3	Electrodischarge machining	Dielectric fluids	Polycyclic aromatic hydrocarbons, benzene, carbon monoxide, nitrous oxide, ozone and aerosols
4	Laser beam machining		Metal fumes, aerosols and radiation, noise
5	Electron beam machining		Metal fumes
6	Ultrasonic machining	B ₄ C, Al ₂ O ₃ and SiC abrasive slurry	Electromagnetic radiation, high frequency noise and abrasive slurry
7	Abrasive jet machining	Abrasives	Abrasive and metal fumes

dust is suspended in the air, it causes adverse pulmonary health effects such as asthma and lung cancer in addition to having harmful impact on eyes and skin.

Liquid droplets in size ranging from 0.01 to 100 μm that are suspended in air during various subtractive processes such as turning, milling, drilling, and grinding are called mist. In wet machining, mist is mainly aerosol suspended in air, causing serious health risks to workers and adding to environmental degradation. Even in minimum quantity lubrication, the mist is prominent due to high pressure air–oil mixture impinging on tools and work material. Volatile hydrocarbons present in cutting fluid are suspended in air due to vaporization and atomization due to heat generated by cutting tools and high mechanical energy used in machining.

A survey in the manufacturing industry indicated that drilling, sawing, and grinding pose higher health risks due to mist formation as compared with turning and milling operations (Fig. 3).

Cutting fluid mists, if inhaled for longer durations, can potentially harm lung functions and cause chronic bronchitis, asthma, and pneumonitis in addition to esophagus, stomach, pancreas, colon, prostate, and rectum cancers. Furthermore, the chips and swarf are the main solid wastes, which are initially hot and may injure workers' skin and eyes. In some instances, swarf may consist of fine iron powder that can burn spontaneously due to rapid oxidation caused by air contact.

Machining noise is a major source of noise pollution in the manufacturing industries, which adds to environmental degradation as exposure to noise level more than 85 dB for an 8-h shift is not acceptable in an industrial environment. A survey shows that subtractive manufacturing industries contribute to 41% of occupational hearing loss cases out of total noise-related cases in Europe.

Apart from traditional processes, several advanced subtractive manufacturing techniques significantly contribute to environmental degradation. In spite of being efficient and accurate machining process, these manufacturing techniques such as chemical machining and electrochemical machining extensively use chemicals that are suspended in indoor air. Moreover, cutting of hard materials takes place at high temperature, which increases concentration of metal fumes, oxides, and aerosols as compared with traditional manufacturing processes. Table 4 illustrates various environmental hazards related to different subtractive manufacturing techniques. Apart from air pollution, plenty of industries dispose of sludge containing heavy metals and chemicals in rivers and lakes, which leads to destruction of flora, fauna, and marine life. Several advanced manufacturing techniques include laser beam, electron beam, and ultrasonic machining.

Outcomes and Future Scope

Although the shift to bulk industrialization and mass production has a positive impact on populations, the adverse effect on the environment caused by manufacturing processes cannot be neglected. There is a tremendous amount of air pollutants evolved during conventional additive manufacturing processes (welding and casting) but their overall contribution is less due to limited use by developed nations. The last two decades have experienced a significant change in the manufacturing industry by introduction of regenerative (additive) manufacturing processes, which are able to reduce environmental degradation. These additive manufacturing techniques such as fused deposition modeling, stereolithography, selective laser sintering, and laminated object manufacturing are however, economical for part production and thus, the need and scope of subtractive manufacturing techniques cannot be ignored especially in the case of mass production. Thus, there is an urgent need for further innovation and research in the environmental aspect of these subtractive manufacturing processes, as in the present scenario, they are a major source of environmental pollution due to the large volume of products produced worldwide.

Food Residue, Loss and Waste as Animal Feed

James D Ferguson, University of Pennsylvania School of Veterinary Medicine, PA, United States

© 2020 Elsevier Inc. All rights reserved.

Introduction

In 2011–2013, world production of food averaged 9.7 billion tonnes (metric tons, FAO Food Balance Statistics) which included alcoholic beverages, cereal grains, dairy products, eggs, fruits, ground nuts, fish and marine products, meats, oil seeds, pulses, root crops, spices, tea, coffee, cocoa, sweeteners, and vegetables. About 49.5% of world food production, 4.8 billion tonnes, was available to consumers. Of the 4.8 billion tonnes of food available for consumption, consumers threw out 1.3–1.6 billion tonnes as food waste (Gustavsson *et al.*, 2011). Some food waste was inedible, but the majority of waste (about 80%) was edible portions. The result is that of food produced only about 35% was consumed by humans. A majority of wasted food was disposed as municipal solid waste to landfills. The consequence is that as the organic food waste decomposes, it contributes about 5% to total CO₂ equivalent emissions and nutrient leachate of N and P, contributing to water pollution (Kaza *et al.*, 2018). Reducing food waste is a first step in to improve sustainability of food production for future generations (Giroto *et al.*, 2015). However, the food system will inevitably produce organic waste, which needs to be more effectively utilized than disposal as MSW. One such use would be to capture food waste as animal feed.

A significant amount of food and food residues are used as animal feed. About 12.8% of food produced over the period from 2011 to 2013 was used directly as animal feed; primarily cereal grains, which are 80% of the food used for animal feed. Twenty two percent (22.2%) of food produced is processed for production of juices and jellies, preserved products, prepared meals, and distilled beverages. Although food processing produces value added products for human consumption, it also produces residues which are largely inedible or not preferred by consumers. The majority of these residues, 95%, are used as animal feed. In addition, some grocery products removed for expired shelf life are collected and combined with food residues as animal feed. Food waste would extend the volume and complement these food losses if included in animal feed, and could reduce the amount of cereal grains diverted to animal feed, extending human food supplies. Projections of world population are that it will increase to 9.7 billion people by 2050, which will necessitate an increase in world food production of 43%. Reducing food waste could significantly contribute to the increase in food availability, whereas utilizing food waste as animal feed could significantly contribute to more efficient food production needed to meet increasing human food needs (Zu Ermgassen *et al.*, 2016).

Globally, it has been recognized that it is critical to reduce food waste and to improve the capture of unconsumed food products to other useful purposes than disposal in landfills (see “Relevant Websites section”). A hierarchy of food loss and waste use has been proposed. First, food waste and losses should be reduced, directly increasing food availability. Secondly, food waste and food residues should be collected and used for animal feed. Thirdly, food waste and food residues not used for animal feed should be composted, and lastly used in anaerobic digestion for energy production (Giroto *et al.*, 2015; Papargyropoulou *et al.*, 2014; Food Waste Reduction Alliance, 2013).

Food Supply Chain and Food Loss and Food Waste

For a detailed discussion of losses and waste the reader is referred to papers by Giroto *et al.* (2015), Hebrok and Boks (2017), Papargyropoulou *et al.* (2014), and Priefer *et al.* (2016). In brief, food reaches consumers through a food supply chain or system (Papargyropoulou *et al.*, 2014). Production begins in the agriculture sector at the farm and is harvested and transported from the farm either to processors and manufacturers or directly to markets. Processors and manufacturers distribute food to retailers, institutions, and restaurants, which provide the final food produced to consumers. The chain can be summarized as producers, intermediaries, and end users. Inefficiencies along all components of the chain result in organic waste (Priefer *et al.*, 2016). Disposal of the waste and the capability to capture waste into animal feed differs along each segment of the food supply system. As food moves from producer to end user, more of the waste ends up as MSW.

Gustavsson *et al.* (2011) partitioned lost food into food loss and food waste. Food loss represented a decrease in edible food mass prior to the end user, whereas food waste was loss of edible components at the end of the food supply chain (Gustavsson *et al.*, 2011). Papargyropoulou *et al.* (2014) suggested that food diverted to animal feed should be included as food loss, as this has a direct impact on reducing food supply to humans. For this paper, food diverted to animal feed will be included in the discussion of food utilized in animal feeding in addition to food loss and waste.

Losses and waste along the food supply chain may be classified into four main streams: food consumable by humans diverted to animal feed (primarily cereals), food residues that result from food processing, food losses that occur due to spillage, spoilage, and transport losses, and food waste that end users dispose. Food diverted into animal feed is primarily cereal grains, which could be used directly by humans. Corn is the primary cereal diverted to animal feed. Food residues result from food processing and manufacturing which lead to by-products not preferable or not consumable by humans. These are residues of cereal, vegetable, and fruit processing such as seeds, hulls, pulp, pomace, and discarded whole fruits and vegetables considered unacceptable for markets. The meat and fish industry produce food residues of condemned and rejected carcasses, blood, offal, and trimmings.

The brewing and distillery industries produce residues of cereal fermentation for alcohol production. The oil industries produce plant meal residues after oil extraction. Many of these residues are used as animal feed.

Food losses represent inefficiencies in infrastructure along the supply chain once food leaves the farm. Spills, spoilage, transport losses result from poor refrigeration and storage at collection points. Losses in transport are due to poor collection vehicles. These losses are difficult to collect unless directly from the manufacturing facility. Losses from processors and manufacturers have a greater opportunity to be collected and used for alternative purposes, thus MSW disposal tends to be low for losses from this sector (BSR, 2013). In addition, processors and manufacturers have significant income from the sale of food residues as animal feeds.

Losses from retailers, restaurants, institutions, and markets present difficulties in collection due to high moisture content, rapid aerobic deterioration, low daily volumes, and spatial distribution of end users. Household food waste presents more problems in collection and handling than waste from retailers and markets. Volume of collection can be significant at grocery stores and markets making collection more efficient. Due to technological collection problems from households, food waste at the consumer end of the food chain results in MSW disposal. In the US, 21% of food waste ends up in landfills. The major challenge at the consumer sector is collection of food waste so it can be diverted to alternative uses such as animal feed. In addition, food waste is high in moisture content and nutrients which result in rapid spoilage, necessitating frequent collection.

Food waste is estimated at 1.3–1.6 billion tonnes annually (Gustavsson *et al.*, 2011). Food used as animal feed is estimated at 1.25 billion tonnes by the FAO (FAO STATS, Food Balance Statistical Summary). Residues of food processing vary by sector for fruit, vegetable, meat, meat, brewing and distilling, and dairy. However estimates from various industries are that residues are 20%–40% of raw food inputs after product production. This would result in 0.40–0.86 billion tonnes of food residues used for animal feed. The animal feed available from these three streams would provide 2.9–3.4 billion tonnes annually.

The Animal Feed Industry

Alltech surveyed the world feed industry in 2013 (All About Feed, 2014). There were 26,240 feed mills in the world producing 963 million tonnes (1062 million US tons) of animal feed. The number one producer of animal feed was China at 189 million tonnes (208 million US tons) from 9500 feed mills, followed by the US with 169 million tonnes (186 million US tons) of animal feed from 5236 feed mills. World-wide, poultry feed is the number one product at 444 million tonnes (489 million US tons) (Table 1). Swine are the second largest feed consumer at 243 million tonnes (268 million US tons) followed by all ruminants at 196 million tonnes (216 million US tons) (Table 1).

Feed produced by feed mills is a dry product, containing 10% or less of moisture. The residues referred to above, 2.9–3.4 billion tonnes, from food waste, food used for feed and food processing residues, contain a significant amount of moisture, except for cereal grains used as animal feed. The equivalent dry tonnage of these residues is more likely to supply 1.6–1.7 billion tonnes of dry animal feed. In addition, feed from feed mills is not the only source of feed for livestock. Forages, pasture grasses, and crops grown on farms supply a substantial amount of feed for livestock in the world. Food waste as animal feed would supplement animal feed sources and not entirely replace all animal feeds.

The major products used in animal feed are summarized in Table 2 based on a paper by Capper *et al.* (2013). Forage crops comprise a major component of herbivore (primarily ruminants) feedstuffs and are not consumed by humans. Other feed items are co-products or waste products of the food processing industries and have variable value as human food sources. Cereal grains are the major food group used in animal feeds which could be consumed by humans.

The utilization of food used in animal feed based on estimates by the Food Agriculture Organization is in Table 3 for the year 2011 (see “Relevant Websites section”). Overall, 13.6% of world food production was used in animal feeds in 2011 (Table 3). Cereal grains comprise the largest component of animal feeds with 34.9% of production going into animal feed,

Table 1 World feed production as reported by Alltech in 2014 for the situation in 2013

Rank	Animal group/Item	Million tonnes	Number
1	Poultry	444.0	
2	Swine	243.0	
3	Ruminants	195.0	
4	Aquaculture	34.4	
5	Pets	20.7	
6	Equine	12.4	
	Total feed mills		26,240

Table 2 Examples of feeds commonly used within U.S. livestock production systems^a

Feed source	Examples	Human edible?
Forage crops	Pasture grasses, alfalfa, clovers, hays, silages (grass or crop based)	No
Cereals	Corn, wheat, barley, millet, sorghum, triticale, oats	Yes
Plant proteins	Soybean (meal and hulls), cottonseed (whole and meal) safflower meal, canola meal, peanut meal	Partially
Vegetable oils	Soybean, canola, corn, sunflower oils	Yes
Grain by-products	Distillers grains (wet and dry), corn gluten, wheat bran, straw, crop residues	No
Vegetable by-products	Apple pomace, citrus pulp, almond hulls, pea silages	No
	Waste fruit/vegetables	Partially
Food industry by-products	Bakery waste, cannery waste, restaurant waste, oils, expired candy, potato chips, bakery products, greases	Partially
Sugar industry by-products	Molasses (cane, beet, citrus), beet pulp	Partially
Animal by-products	Meat and bone meal, tallow, feather meal, bloodmeal, poultry litter	Partially
Dairy by-products	Milk, whey products, casein	Partially
Marine by-products	Fish and seafood meal and oils, algae	Partially

^aCapper *et al.* (2013).**Table 3** Major food groups used in animal feeds^a

Food group	Production	Animal feed	% of production	% of food used for animal feed
	Metric tonnes	Metric tonnes		
Cereals	2,345,593	818,837	34.910	64.898

Offals	18,151	1041	5.735	0.083
Totals	9,288,281	1,261,738	13.584	100.000

^aFAO Stats (accessed October 2014). Available at: <http://faostat.fao.org/>.Note: FAO, 2011. Food Balance Sheets. Food and Agriculture Organization. Available at: <http://faostat.fao.org/site/368/default.aspx#ancor> (accessed August 2018).

representing almost 65% of animal feeds (**Table 3**). Starchy roots (22.2% of production) and pulses (19.4% of production) were the next largest contributors to animal feed based on production totals. Slightly over 15% (**Table 2**, 15.7%) of fish and seafood production was used for animal feed, but it comprised only 1.86% (**Table 2**) of total animal feeds. Milk and milk products were a significant contributor at 6.26% of animal feeds and 10.68% of total production (**Table 2**). Oil crops, such as soybeans, cottonseeds, and rape seed, contributed 6.46% of total production to animal feed, but were only 2.82% of animal feed (**Table 3**). The data suggest that only reducing cereal grains in animal feeds would have a significant benefit to human food supply. If all cereal grains were diverted from animal feed, it would increase human food supply about 1 billion metric tonnes, about 50% of the needed increase in food supply by 2050.

Table 4 looks more closely at the use of cereals and other animal products in animal feeds. Of cereals used for animal feed, maize was 59.25% of all cereals (**Table 4**). Wheat (17.35% of cereals used in animal feeds, **Table 4**) and barley (10.92% of cereals in animal feeds, **Table 4**) were the next major cereals used in animal feeds. A little over half of maize production (54.75%, **Table 4**) was used for animal feed, whereas 69.3% of oat production and 71.5% of other cereals were used for animal feed, but these cereals were less than 4% of all cereals used as animal feeds. The cereal grains barley (67.294%) and oats (69.285%) were primarily used for animal feed (**Table 4**) but their total contribution to animal feed was only 10.92% and 1.89%, respectively (**Table 4**). Cassava, followed by potatoes and sweet potatoes were the most common starchy roots used as animal feed (**Table 4**). Of oil seeds, soybeans and cottonseeds were the major co-products used in animal feeds (**Table 4**).

Table 4 Utilization of agricultural products for animal feed

Note: FAO, 2011. Food Balance Sheets. Food and Agriculture Organization. Available at: <http://faostat.fao.org/site/368/default.aspx#ancor> (accessed August 2018).

For vegetables, fruits, and meat small percentages of total production was used in animal feed (Table 4). These amounts would represent cull products that were excluded from processing or sale from retail markets. Very little of food production of vegetables, fruits, and meat were used as animal feed. Animal feed from these products typically is from co-products of food processing and not direct diversion of these foods to animal feed.

Table 5 presents the utilization of by-products from food processing and cereal grains used for animal feeds in the US in 2012 (NASS publication). Consistent with the FAO data, cereal grains are the major item used as animal feed with food processing residues comprising 25.8% of livestock feeds. The majority of co-products used as animal feed are from the vegetable oil industries from the processing of oil seeds, producing oil seed meals, which typically are high protein feeds (Table 5). However these estimates do not include vegetable, citrus, bakery, candy, chip and other food waste which comes from retailers and juice and vegetable processors.

Co-Products of Processing Industries

Data from [Crawshaw \(2001\)](#), [Macgregor \(1989\)](#), and the [National Research Council \(2001\)](#) is summarized in [Table 6](#) for co-product feeds typically used in ruminant and swine diets. As Crawshaw has pointed out, the production of feed grade co-products inevitably increases as higher standards are imposed on foods for human consumption. Thus, we may expect feeds from these co-products to increase in production as more rigid standards are applied based on appearance, uniformity in size, absence of defects, and lower contamination thresholds in human food regulations. Presented in table six are values for dry matter (DM), crude protein (CP), neutral detergent fiber (NDF), starch, fat, ash, and metabolizable energy for ruminants (ME, MJ/kg, (Mjoules/kg)) ([Table 6](#)). For comparison, fine ground corn has an energy value of 14.4 MJ/kg on a DM basis whereas alfalfa hay has a value of 7.8 MJ/kg. Most co-products have an energy value slightly lower than ground corn, unless they have a significant fat content, but have a higher energy value than most forages. However, as seen [Table 6](#), many co-products have low DM content and, unless excessive water is removed, present a problem in transport and storage due to low aerobic stability. Removal of water is necessary to economically transport co-products to farms or feed mills which may be located at some distance from the processing plant. In addition a dry product is necessary to improve stability and handling.

Co-products from processing industries are an important source of revenue and comprise the greatest food waste source for animal feed. Processing plants provide a large volume of residues at a defined location, improving the efficiency of collection. However, residues of processing have a high moisture content and may be located some distance from farms that may use the product. This facilitates collection, but challenges distribution. Removing moisture adds to handling and processing costs, increasing the cost of the co-product. Co-products in [Table 6](#) include items such as pomace or pulp from the canning and juice industries, secondary products of the ethanol, spirits, brewing or oil industries, expired bakery, vegetable, and candy products, and residues of the rendering industry. Most of these items would only be partially consumable by humans, but would not be preferred food items. Livestock industries provide a valuable resource for disposal of these items as opposed to municipal disposal or incineration. Livestock convert typically poor quality residues into high quality animal protein for human consumption.

Food Waste From Retail, Restaurant, and Household Sectors

The reader is referred to a paper by [Dou et al. \(2018\)](#) for a comprehensive review of the feasibility and challenges of feeding food waste to livestock. Historically swine have been the preferred animal for food waste feeding ([Dou et al., 2018](#); [Salemdeeb et al., 2017b](#)). Swine are omnivores and can handle diverse feed inputs. However, fish, poultry, pets, and ruminants may also be fed food waste, but with limitations on total quantity in the diet. In 1995 the National Animal Health Monitoring Service ([USDA, 1995](#)) estimated that 3.9% of hog farms in the US were feeding food waste based on a sample of 418 operations in 1995.

In 2012 NAHMS sampled small hog farms (< 100 hogs/farm, 534 farms sampled) for feeding practices. On hog farms with 50–99 hogs (460 farms sampled), 12.0% were feeding table-food waste, whereas on farms with 1–49 hogs (79 farms sampled),

^aFrom [Crawshaw \(2001\)](#).^bFrom [Macgregor \(1989\)](#).

23.6% were feeding table-food waste. Table-food waste was not listed as a feed component on large swine farms (> 100 hogs/farm), despite feeding a variety of food processing by-product feeds. Small hog farms feeding table-waste is historical; hogs were often kept on family farms to utilize household food waste. This practice is still common on small hog farms throughout the world. However, the hog industry has intensified into larger units with more mechanized feeding systems, which dictates that feeds need to be dry and handled in bulk. Commercial feed sources composed of cereal grains, oil seed meals, and byproduct feeds are more easily handled in these systems and dominate feed supply. Westendorf (reported in [Dou et al., 2018](#)) observed that fewer swine farms were feeding food waste in New Jersey in 1994 than in 1964, 36 farms versus 250 swine farms, respectively. Commercial mills need to utilize feeds which can be easily handled in bulk, stored in bins and combined in mixers, which necessitates using dry feeds. In addition, feed efficiency (feed to gain) and time to slaughter are critical components of efficiency on large swine operations. Large swine operations are under pressure to utilize cost effective feeds which are consistent in nutrient

content and quality. Cereal grains and food residue by-products provide dry, consistent feed ingredients. Whereas food waste is wet and variable in nutrient content and difficult to handle.

Feeding of food waste from retailers, restaurants, institutions, and households presents challenges in collection, processing, distribution, safety, and acceptance by consumer and producer. Currently, other than in South Korea, Japan, Taiwan, and Thailand (Zu Ermgassen *et al.*, 2016), little food waste is used in animal feed. Worldwide only 4%–5% of food waste is used in animal feed due to difficulties of collection, risk of disease, and variation in nutrient content. Collection presents difficulties from residential households without central collection points. Variation in household food inputs into waste creates variation in nutrient content. High moisture content increases risk of spoilage. Meat residues in food waste are a risk for viral, bacterial, and nematode diseases for livestock consuming unprocessed waste. To reduce the risk of disease, some have recommended only utilizing fruit and vegetable waste as the sole source of animal feed, but these waste products are low in protein content which would limit inclusion rates and eliminate substantial amounts of food waste from re-feeding (San Martin *et al.*, 2016). Collection, nutrient variation, moisture content, and disease risk must be controlled to utilize food waste as a viable animal feed.

To utilize food waste efficiently as a livestock feed requires handling capabilities either at feed mills or directly on farms and methods to control disease and reduce moisture. Although swine are the most common livestock fed food waste, food waste may be fed to fish, pets, poultry and ruminants as long as appropriate inclusion rates in rations are followed. On dairy farms, waste with a high moisture content, such as brewer's grains and fruit and vegetable waste, can be handled more readily than on swine and poultry farms, as commodities can be stored in bulk in open trenches and incorporated into total mixed rations without drying using a feed mixer wagon. Since total mixed rations on dairy farms typically are about 50% dry matter, the high moisture content in food waste is not a problem as long as inclusion rates are limited to a maximal inclusion rate of about 20%. The challenge on dairy farms is to utilize food waste at a sufficient rate that spoilage of stored product is minimized. This often requires small volumes of product be delivered frequently, about once a week, and at volumes that can be fed out within a week. Therefore, sources of wet food waste need to be located in close proximity to the farm utilizing the waste.

Beef farms also can utilize wet food waste or wet by-products such as wet distiller's grains or brewer's grains. Similar issues apply, as high moisture feeds can limit feed intake if they are too high a proportion in the total ration. Wet feeds spoil rapidly if not used at a sufficiently rapid rate. Wet food waste can be ensiled to improve storage, but fermentation takes time to achieve a low enough pH to stabilize the material. Extremely wet material creates seepage during the ensiling, and needs to be collected to prevent environmental spillage.

Disease Risks Feeding Food Waste

A detriment to feeding food waste from end consumers to ruminants is contamination with ruminant meat, which is prohibited due to disease risk of Bovine Spongiform Encephalopathy. Bovine Spongiform Encephalopathy, (BSE) is a neurologic prion disease of cattle, which was spread in the United Kingdom through feeding meat, brain and spinal cord residues to cattle. Not only was this a risk to cattle, but humans consuming meat produced from cattle consuming meat meal were at risk for developing a variant of Creutzfeldt-Jakob disease (CJD), a rapidly progressive, invariably fatal neurodegenerative disorder related to BSE. Therefore, household waste, restaurant, and institution plate waste are not acceptable as ruminant livestock feed due to ruminant meat contamination.

In addition to BSE, animal products pose a significant feed safety risk due to viral and bacterial contamination for all livestock consuming food waste. Animal products may harbor food born bacteria, such as *Salmonella*, *E. Coli*, *Listeria*, and *Corynebacteria* spp. Contamination with viruses such as Foot and Mouth Disease, African Swine Fever, and Swine Vesicular Disease and parasites such as *Trichinella* pose significant risks when feeding food waste with meat products.

Due to disease risk, the European Union has banned feeding food waste to livestock. Disease outbreaks in the United Kingdom (UK) associated with food waste feeding are fresh in people's minds (Luyckx, 2018). In 2001, Foot and Mouth Disease occurred due to a swine farm illegally feeding poorly processed food waste, which led to significant livestock condemnation to eradicate the virus. Thousands of livestock were destroyed to stop the outbreak and eradicate the virus from the UK. Total costs were estimated at £8 million British pounds (Luyckx, 2018). Feeding ruminant meat meal to cattle lead to outbreaks of BSE between 1986 and 2001 in the UK, with cases of variant CJD in humans linked to consuming infected beef. Due to the long incubation period of BSE in cattle, infected cows could go to market with no obvious signs of infection. Meat from infected but normal appearing cattle became a source of variant CJD disease in humans. Thousands of cattle in Britain were slaughtered and rendered to remove the risk of eating contaminated beef by humans.

To control disease risk requires strict regulations and oversight (Dou *et al.*, 2018). The most common approach is to heat food waste to inactivate bacteria and viruses (Zu Ermgassen *et al.*, 2016). In the US, feed mills must be licensed to process food waste for animal feed and have facilities to heat food waste to 100°C for at least 30 min (US Swine Health Protection Act, 1980). Heating may be either steam injection or direct fire cooking, with continuous agitation of the waste to ensure uniform heating. There are only 2722 licensed facilities in the US. These facilities produce 266,104 tonnes (293,330 US tons) of swine feed, which is only 0.6% of all swine feed sold in the US.

South Korea and Japan have implemented control programs which cook food waste to prevent disease. Pasteurization of food waste destroys pathogens and allows safe feeding. Food wastes are treated for three minutes at 80°C, or 30 min at 70°C, enough to deactivate viruses such as foot-and-mouth. Since the introduction of these regulated systems, no disease outbreaks have been associated with swill feeding in these countries (Zu Ermgassen, 2016; Luyckx, 2018). The ban on feeding food waste in the EU may

need to be re-evaluated for future sustainability. Licensing feed facilities and regulation to ensure pasteurization of food waste can be employed to ensure food safety with waste that includes meat scraps.

Some have recommended using only plant based food waste in animal feeds to reduce disease risk. However, fruit, vegetable, and cereal products may also pose a health risk when used in animals feeds. Plant by-products may be a source of mold toxins, bacterial toxins, and other contaminants. Mold toxins may be produced prior to harvest or post-harvest if grains are not properly stored at appropriate moisture content. Typically moisture content below 20% will protect most grains from post-harvest mold growth. Pre-harvest fungal invasion of the grain may occur from insect damage, drought conditions and other stresses to the plant in the field. Mycotoxin(s) may be present in the grain at harvest from conditions in the field which encourage spore invasion and growth within the grain head. Threshold levels of mycotoxin concentration in grains make it illegal to use these grains in human foods and in animal feeds. Bacterial contamination is possible when moisture content is above 30% in grains and food waste. Bacterial growth under aerobic conditions causes spoilage and loss of nutrient content and is a significant problem in utilizing high moisture food residues. High moisture content and anaerobic conditions can lead to growth of *Clostridia botulinum* and botulism toxin contamination of food wastes.

Bacteria, bacterial and mold toxins, viruses and parasites are not the only health risk when feeding food waste and residues. Food waste may contain residues of heavy metals and pesticides. Pesticide residues may be high due to inclusion of peels and rejected fruits in waste. Heavy metals may be increased due to contamination from collection vessels. San Martin *et al.* (2016) tested for residues of metals and pesticides (and mycotoxins) and found contamination risk was low in fruit-vegetable waste and fish waste. However, Garcia *et al.* (2005) found lead and cadmium at high concentrations in restaurant and household food waste, which means surveillance of potential toxic materials needs to be in place. Monitoring of toxic content of mold toxins, pesticides, and heavy metals should be a best management practice in food waste feeding systems. In addition to prevent spoilage prior to processing, collection needs to be timely and containers cleaned between loads. This creates logistic problems when collecting household food waste. San Martin *et al.* (2016) proposed a series of technologies be in place to safely use food waste as animal feed. These include consistent feed evaluation and testing, processing to reduce moisture and prevent disease, and incorporation in diets to achieve a consistent feed product for consistent production of meat quality.

Variation in Nutrient Content in Food Waste

Moisture content may be 70%–80% in food waste, which makes them extremely unstable at ambient temperatures. The high moisture content necessitates frequent collection and safe storage conditions. San Martin *et al.* (2016) observed that fruit and vegetable waste was acceptable over several days collection when stored in bins at markets despite the high moisture content. In addition to high moisture content which can decrease stability over time, household and restaurant food waste may contain a significant concentration of fat, which may be prone to rancidity if not stored appropriately.

Although food waste has nutrient values acceptable for livestock feeding, variation in moisture content, protein, fat and minerals make it challenging to achieve comparable growth rates when included in swine diets. Wet food waste fed as the sole source of feed in swine diets limits feed intake and slows rates of gain (Westendorf and Myer, 2004). In addition, feeding food waste as the sole source can have a negative impact on meat quality due to high polyunsaturated fatty acid and salt content (Choe *et al.*, 2017). Limiting the amount of food waste included in total diets can achieve consistent meat quality and rates of gain. Márquez and Ramos (2007) found no negative effects on organoleptic quality when food waste from fruit and fish shops was included in finishing diets at 17% of total diet and nutrient content was comparable to control diets. Zu Ermgassen *et al.* (2016) in a summary of published feeding trials found no negative impacts on meat quality when diets were appropriately formulated to meet nutrient requirements.

However, Zu Ermgassen *et al.* (2016) reported that inclusion of 50% food waste in pig diets would reduce growth rates by 13%. To offset the slower growth rates, the cost of feeding food waste in swine diets would need to reduce feed costs to compensate for the longer days on feed. Food waste feed sources are 40%–60% lower in price compared with conventional feeds used in swine diets in Japan (Zu Ermgassen *et al.*, 2016). Average conventional feed price was 58.87 yen/kg compared with 25.32 yen/kg for dry food waste and 25.53 yen/kg for liquid food waste (Zu Ermgassen *et al.*, 2016). However, the cost of the total diet will depend on the amount of food waste blended into the total feed offered. It requires about 328–340 kg of feed to finish a hog over a 6 month period using conventional feeds. If including food waste increases time to finish by 13%, which will increase total feed consumed, then the lower cost of the diet including food waste would need to offset the higher feed volume and longer time to finish. At Japanese feed prices, food waste would need to be at least 23% of the feed to be economically attractive in swine finishing rations. However, total societal benefits and risks should be considered in assessing the utility of using food waste in feeds fed to animals.

The reduction in growth rates in swine fed food waste occurs for two reasons. The first is the high moisture content which can depress feed intake (Westendorf and Myer, 2004). The second is the variation in nutrient content (Garcia *et al.*, 2005; Westendorf *et al.*, 1999; Westendorf and Myer, 2004). The variation in nutrient content in food waste has been demonstrated in multiple studies (Dou *et al.*, 2018; Esteban *et al.*, 2007; Garcia *et al.*, 2005; San Martin *et al.*, 2016; Salemddeb *et al.*, 2017a; Westendorf and Myer, 2004; Westendorf *et al.*, 1999). The variation in crude protein content of food waste compared with variation in soybean meal and corn and other common by-products serves as an example of the challenge in using food waste in livestock rations. Soybean meal and corn have a coefficient of variation (CV) of protein content of 1.3% and 9.0%, respectively whereas household food waste is reported to have a CV for protein content of 24.4%, 27.4%, and 29.4%. Drying household waste does not reduce the variation in protein content. Institutional food waste (CV of CP from 20% to 57%) and restaurant waste (CV of CP from 23.3% to 37.5%) were as variable as household waste.

Even fruit and vegetable waste had a CV for protein content of 31%. Along with CP variation, concentration of other nutrients also vary, such as fat, fiber, ash and carbohydrate content. This makes it challenging to maintain a consistent nutrient content in the final diet delivered to the farm without rapid analysis of nutrient content in the collected food waste.

Variation in protein and other nutrients occurs due varying proportions of food inputs (varying fruits, vegetables, cereals, pulses, and meat), cooking practices (grilling, roasting, frying), and seasoning (salt and other spices). Food waste will vary in nutrient content due to differences in household food preferences and from restaurants and institutions as meals vary throughout the week. Furthermore, food waste from supermarkets, farm markets, restaurants, and households will vary in nutrient content due to variation in commodities in the waste. [Hebrok and Boks \(2017\)](#) reported that fruits, vegetables, bread and bakery products were the most wasted food in households, but dairy and meat sources were also common. Household food waste contains products with high carbohydrate content and low protein content (fruits, vegetables, breads and bakery products) along with variable amounts of products that are high in protein and fat content, but low in carbohydrate content (meat and milk). Mixing food waste with other feed commodities can be utilized to minimize variation in nutrient content, but this requires rapid analysis of nutrient content and storage facilities to separate and re-blend waste products to achieve consistent nutrient values. Rapid analysis of nutrient content in food waste using near infrared spectroscopy can allow for more precise incorporation of food waste into animal feed to achieve a consistent final product.

Due to high moisture content and its negative effects on feed intake in livestock, food waste is best utilized after dehydration ([San Martin et al., 2016](#)). Removing moisture aids in handling food waste. Dried food waste can be mixed with other feeds to improve the consistency of nutrient content. It is more cost effective to truck dry feed to farms than wet feeds, especially over long distances. In addition [Esteban et al. \(2007\)](#) observed that heating fruit-vegetable waste and fish waste improved digestibility as long as temperatures were $<105^{\circ}\text{C}$. If heating is excessive digestibility is reduced due to formation of carbohydrate and protein complexes. Dehydrating food waste can inflate costs to utilize food waste in livestock feeds, therefore there is a trade off in utility of handling with higher cost of processing ([Salemdeeb et al., 2017b](#)). Wet food waste is best used when collected near the farm and directly transported to the farm. Urban centers can more strategically collect food waste centrally, dry, grind and combine with other feeds to transport across greater distances to livestock facilities or feed mills.

Value in Feeding Food Waste to Livestock

Re-feeding food waste to animals is the preferred method of disposal after reduction and diversion to food banks, compared with composting and anaerobic digestion ([Salemdeeb et al., 2017b](#)). Composting and anaerobic digestion are commonly used to prevent disposal in landfills, particularly in the EU which bans livestock feeding ([Salemdeeb et al., 2017a](#)). Which method provides better overall environmental benefits was examined by [Salemdeeb et al. \(2017a,b\)](#). They performed a life cycle analysis for wet food waste feeding, dry food waste feeding, composting, and anaerobic digestion. Wet food waste feeding provided the greatest benefit to the environment, with dry feeding a close second. Benefits were realized because food waste replaced significant amounts of conventional feeds. They estimated that 20% of EU pork production could be supported by incorporating food waste into swine diets. One tonne of wet food waste could replace 109.5 kg of dry feed in swine diets. Similarly, [Zu Ermgassen \(2016\)](#) estimated that feeding food waste in the EU would reduce the land needed to support pig production by 1.8 million hectares. Feeding food waste frees up available land for food production for human consumption. Even with drying food waste, increasing local cost and associated emissions, the benefits in reducing conventional feed inputs create a global benefit in reducing the environmental foot print of livestock feeding.

To encourage use in animal feed, government subsidies and regulated programs may be needed to induce food waste feeding. [Priefer et al. \(2016\)](#), although not directly describing animal feeding, discusses incentives and regulations governments may need to employ to encourage diversion of food waste from MSW to animal feed, or other more sustainable uses. South Korea has implemented a policy of consumer separation of house hold waste into three categories: food waste, recyclable waste, and other waste, which has significantly reduced organic MSW. Consumers pay for food waste disposal and are fined if they are in noncompliance ([Priefer et al., 2016](#)). Policies in Japan and South Korea have resulted in significant amounts of food waste going to animal feed. In Japan 52.5% of food waste from manufacturing, retail, and catering industries is used in animal feed ("Ecofeed"; [Dou et al., 2018](#); [Zu Ermgassen et al., 2016](#)). Ecofeed comprises 5.8% of all concentrate fed (2014 data) on pig, poultry and ruminant farms in Japan ([Zu Ermgassen et al., 2016](#)). No household food waste is included in Japan re-feeding, but South Korea incorporates household waste in animal feed. Due to concerted government effort, 42.5% of all food waste is recycled as animal feed ([Dou et al., 2018](#); [Zu Ermgassen et al., 2016](#)). Government regulation, tight oversight, and continuous monitoring in Japan and South Korea demonstrate food waste can successfully be utilized in livestock diets.

The Food Waste Reduction Alliance (FWRA) in the US was formed in 2011 under the auspices of the Grocery Manufacturers Association (GMA), the Food Marketing Institute (FMI), and the National Restaurant Association (NRA) (see "Relevant Websites section") The alliance includes more than 30 manufacturing, retailing and foodservice companies and expert partners from the anti-hunger community and waste management sectors (see "Relevant Websites section"). The FWRA commissioned BSR to conduct and analyze a survey they designed to assess food waste among food manufacturers, retailers, and wholesalers ([BSR, 2013, 2014](#)). Two surveys were completed, Tier I and Tier II.

In the FWRA surveys food waste from the manufacturing sector was 20.09 million tonnes (44.3 billion US lb.); only 1.09 million tonnes (2.4 billion US lb.) was disposed in MSW. The majority of food waste was diverted to animal feed, 13.88 million tonnes (30.6 billion US lb.). Next greatest diversion from land-fills was land application at 3.81 million tonnes (8.4 billion US lb.).

Only 0.32 million tonnes (0.7 billion lb.) of manufacturing food waste was donated for food consumption. A survey of the retail sector estimated food waste was 1.72 million tonnes (3.8 billion US lb.) of which 0.77 million tonnes (1.7 billion US lb.) was deposited as MSW. Only 0.24 million tonnes (0.53 billion US lb.) was recovered as animal feed from the retail/wholesale sector, but 0.72 million tonnes (1.59 billion US lb.) was used for food donation and composting from this sector (Tier 1 and Tier II BSR survey, 2013). Restaurant respondents donated or recycled 15.7% of food waste, largely recycled cooking oil (BSR, 2014). However, 84.3% of restaurant waste went to landfills with an annual food waste of about 14,969 tonnes (33 million US lb.) (BSR, 2014). The consumer sector, households, grocery stores, restaurants, and cafeterias contribute the major amount of food waste to MSW in the US (and in Europe, (WRAP)). This is the major sector to focus on to reduce landfill disposal of food waste.

Conclusion

Food waste can be used as a significant source of animal feed and can be a reasonable energy or fiber source and replace cereal grains to a variable extent in animal diets. Food processing waste is easier to incorporate into animal feed due to concentrated points of collection and processing to remove water. Restaurant and retail food waste are more difficult to include in animal feed due to dispersed points of collection, and higher animal food content, which requires special processing to be used in animal feeds. High moisture content increases transportation and handling costs. Aerobic spoilage is a higher risk with high moisture content. High moisture content can limit feed intake. Variable content of sources of waste products incorporated into food waste can cause significant variation in nutrient content which limits extent of inclusion in animal diets. However, inclusion of food waste in livestock diets could displace food consumable by humans that is currently fed to livestock, primarily cereals. This would have benefits environmentally, socially, and economically in total human food supply.

Impact of Environmental Initiatives on Environmental Performances: Evidence From the UK Manufacturing Sector

Prithwiraj Nath, Leeds Beckett University, Leeds, United Kingdom

Ramakrishnan Ramanathan, University of Bedfordshire, Bedfordshire, United Kingdom

© 2020 Elsevier Inc. All rights reserved.

Introduction

Being sustainable is one of the key objectives of business today. Pressure from various stakeholders such as customers, suppliers, employees, institutional investors, or policy makers has been made to adopt sustainability initiatives a priority for business. However, often firms are skeptical on how to approach sustainability, what could be the best combination of initiatives that each firm should adopt based on their own circumstances, or how this could affect their environmental footprints. The findings of previous research to such questions are often ambiguous and contradictory. For example, one stream of research suggests that environmental initiatives have positive influence on firm performance both financially and environmentally. Such studies suggest a “win-win” argument and show that the benefits of any such initiative is larger than its cost (e.g., [Porter and van der Linde, 1995](#); [Montabon et al., 2007](#)). On the other hand, another stream of studies shows that any environmental initiatives can lead to uncertainties in the operations of an organization, generate unforeseen costs, and not all firms are capable of adopting a proactive green strategy as any such initiatives is contingent on certain firm characteristics such as its environmental commitment or resource capabilities (e.g., [Aragon-Correa et al., 2003](#); [Berrone and Gomez-Mejia, 2009](#)). Therefore, managers are often unsure about how to approach and adopt environmental initiatives within their organization, should they adopt a leadership role or a “wait and watch” strategy towards their environmental responsibilities, and how any such initiative leads to enhanced environmental performance.

The UK, being an advanced and developed nation, must take responsibility towards leading the environmental initiatives among the other industrialized nations. However, the data tell a different story. A recent study shows that the UK is the 8th largest emitter of greenhouse gas, and that each person in the UK population consumes energy twice the global average ([London Climate Change Migration, 2018](#)). There are several reasons why the UK is not able to fulfill its leadership role to tackle environmental challenges. Extant research shows that the UK manufacturing industry responds to environmental demands in an economically driven, reactive fashion with concern for bottom-line rather than any strategic objectives to achieve competitive advantage. For example, early studies in environmental research in the UK context shows short-term dividends drive environmental strategies for UK firms and many such firms adopt environmental initiatives to comply with the regulations and avoid penalty ([Ghobadian et al., 1995](#); [Strachan et al., 1997](#)). Even recent research shows that UK manufacturers adopt short-term pollution control views with a focus on cost saving rather than a long-term environmental strategy ([Dahlmann et al., 2008](#); [Nath and Ramanathan, 2016](#)). However, as environmental regulations have a significant impact on manufacturers, UK firms need to have strategic thinking on how to respond to such regulations. Thus, it becomes imperative to investigate how the UK manufacturing industry at present views and adopts environmental initiatives; and how long-term environmental performances play a dominant role in their business strategies. In this study, we address these issues in two stages: (1) identify and measure the relationship between various environmental initiatives and performances, and (2) explore how UK manufacturers can develop their long-term sustainability strategies based on such association.

The structure of the paper is as follows. The next section discusses the background theory and constructs of the conceptual framework. We then discuss the methodological framework. The last section discusses the results and implications of this study.

Conceptual Framework

Environmental Initiatives

An organization's environmental initiatives are characterized by its motivation, sensitivity, and response towards changes in the environment ([Dahlmann et al., 2008](#)). An organization adopts such initiatives to respond to three interrelated pressures. First is the economic pressure, such as the potential cost savings that might arise from tackling resource inefficiency. Second is the stakeholder pressure, which includes everything from regulations through to shareholder resolutions and customer demand. Third, is the strategic pressure, which involves the desire for the firm to position it as being environmentally conscious.

Environmental management literature broadly classifies environmental initiatives as strategic and tactical ([Montabon et al., 2007](#); [Nath and Ramanathan, 2016](#)). Strategic environmental initiatives involve coordinated planning, and implementation of controls established by top managers. It involves practices such as long-term environmental plans, and integration of environmental policies with business objectives. Tactical environmental initiatives, on the other hand, involve internally focused environmental management exercise that pertains to shop floor practices. It involves initiatives related to structural changes in operational systems such as change in plant capacity, production equipment, and production technology to contain waste in production process.

Fig. 1 Conceptual framework for investigation of relationship between environmental initiatives and environmental performances.

Environmental Performance

Environmental management literature broadly classifies environmental performance into three categories: Pollution control, pollution prevention, and supply chain coordination (Berrone and Gomez-Mejia, 2009; Montabon *et al.*, 2007; Nath and Ramanathan, 2016). Pollution control refers to end-of-pipe technology that captures, treats, and disposes of waste at the end of production process. Pollution control is a short-term compliance strategy that relies on pollution abatement. Such hazard control technology is often an environmental objective for firms that do not have resources to implement new environmental technologies. Pollution prevention, on the other hand, aims to minimize pollution at various stages of the production process and requires structural investments in product and process redesign (Klassen and Whybark, 1999). Pollution prevention is often the environmental objective for firms with superior resource base as it offers a unique competitive advantage. Supply chain coordination involves how a manufacturer works with its suppliers and contractors together to achieve a common environmental goal.

Environmental Initiatives and Environmental Performance

Exploring the role of environmental initiatives on environmental performance is not straightforward. For instance, Darnall *et al.* (2005) draw on the resource-based view of the firm and suggest that the adoption of environmental management systems might be with the genuine intention of improving environmental performance (and thus business performance). Alternatively, they reason, espoused environmental concern may be little more than a symbolic gesture to appease various pressure groups (for instance, stakeholders such as employees, shareholders, and so on). Such practice might also be undertaken with a view to preempting future environmental regulation or might be part of a strategic need to be “seen to be green,” thus wooing environmentally conscious consumers. The phenomenon of “green washing” where a firm makes unsubstantiated environmental claims is widely practiced in industry.

Environmental studies in the UK context also report such conclusions. For example, Dahlmann *et al.* (2008) find that the motivation for environmental concern amongst firms in the UK is chiefly economic, rather than regulatory or strategic or as a response to various stakeholder pressures (this finding is in line with that of earlier UK surveys such as Ghobadian *et al.*, 1995; Strachan *et al.*, 1997). In such cases, it seems that there is little reason to suppose that the mere fact of environmental rhetoric from top management in a company will be a guarantor of genuine improvements in environmental performance. Nath and Ramanathan (2016) in their study observe that UK manufacturers focus on tactical initiatives to achieve short-term pollution control objectives. However, when there is significant pressure from external market stakeholders such as customers and suppliers, such firms go beyond the “compliance” goals and adopt strategic environmental initiatives to achieve long-term pollution prevention objectives.

Thus, the motivation for this study is to establish whether the adoption of environmental management strategies and supposed environmental concern do in fact lead to improved environmental performances. Fig. 1 illustrates the conceptual framework for the study.

Methodology

Data Collection

Sustainability researchers have used a variety of approaches to collect data for their studies. For instance, a large number of studies use objective databases such as Toxic Release Inventory (TRI, 1988) or use subjective approaches like managerial surveys or case studies. However, such approaches have their own drawbacks. For example, objective databases on environmental initiatives and performance are not available widely in the public domain in many countries. Often such databases are incomplete or not authentic due to the lack of stringent policy controls. Self-reported surveys or case studies also suffer from drawbacks as respondents can either underreport an undesirable environmental behavior or even overreport certain environmental initiatives to maintain social desirability bias. To overcome such issues, we adopted a novel method of content analysis of the annual and environmental reports that are available publicly and are duly audited from the corporate websites. Content analysis is a systematic tool to analyze a piece of text to investigate if certain words or concepts are within the text (Nath and Ramanathan, 2016).

The study hired three trained researchers who collected the electronic reports from corporate websites, searched for a list of keywords or key phrases, read around the area where such keywords/phrases are mentioned, and subjectively evaluated the involvement of the firms based on their environmental initiatives and performances. We developed the list of keywords/phrases based on an extensive literature review (based on Klassen and Whybark, 1999; Montabon *et al.*, 2007; Nath and Ramanathan, 2016). Each item was measured using a 5-point Likert scale (1 = strongly disagree, 5 = strongly agree) and used a time lag of one year between the reports that were used to evaluate the environmental initiatives and to measure performances. This is necessary as the effects of any environmental initiatives on performances are not instant. Based on the data availability, the final sample consisted of 76 top UK manufacturing firms (based on their revenue figures) from 8 different sectors (SIC 28–35). Table 1 shows a brief summary of the companies studied.

Analysis Methodology

The analysis involved two stages. In the first stage, we used exploratory factor analysis to identify appropriate constructs and organize the content analysis data. In the second stage, we used canonical correlation analysis (CCA) to identify the relationships between the latent constructs. CCA measures the interrelationship between a linear combination of independent variables (called the independent variate) and a linear combination of dependent variables (called the dependent variate). CCA chooses the weights for the linear combinations to maximize the correlation between the independent and dependent variates. Since the objective of this study is to understand the relationship between multiple independent environmental initiatives variables (strategic and tactical) and multiple dependent environmental performances variables (pollution control, pollution prevention, and supply chain coordination), CCA is the appropriate tool (see Hair *et al.*, 1998 for an excellent primer on CCA).

Results

Stage 1: Factor Analysis

Principal component analysis with varimax orthogonal rotation on the list of 34 environmental measures shows that the items are loaded on five factors explaining 76.35% of the variance (see Table 2 for the list of items under each construct and the items that are deleted due to poor or multiple loading on more than one construct). The five-factor structure corroborates the conceptual framework of this study.

Table 2 Principal component analysis of the scale items

Item (based on Klassen and Whybark (1999), Montabon et al. (2007) and Nath and Ramanathan (2016))	Mean (SD)	Strategic initiatives (Cronbach's alpha $\alpha = 0.92$)	Tactical initiatives ($\alpha = 0.89$)	Pollution control ($\alpha = 0.84$)	Pollution prevention ($\alpha = 0.96$)	Supply chain coordination ($\alpha = 0.87$)
Reward for environmental project	2.42 (1.75)	0.691				
Integration with long-term business strategy	2.36 (1.78)	0.717				
Explicit definition of environmental policies	2.55 (1.86)	0.754				
Environmental mission statement	2.39 (1.78)	0.717				
Strategic alliances for environmental projects	2.13 (1.61)	0.704				
Employee environmental training ^a	2.26 (1.72)	–				
Market surveillance for environmental issues ^a	3.0 (1.26)	–				
Cross-functional cooperation for environmental improvements ^a	2.65 (1.85)	–				
Money spent on environmental initiatives ^a	2.47 (1.82)	–				
Environmental audits	3.05 (1.93)		0.593			
Environmental participation such as ISO 14001, EMAS	3.0 (1.78)		0.566			
Environmental risk analysis	2.44 (1.80)		0.650			
Environmental management system	3.18 (1.82)		0.648			
Dedicated environmental department	2.96 (1.80)		0.521			
Continuous improvement in environmental standards	2.97 (1.80)		0.657

Environmental standard for supplier	2.55 (1.81)					0.683
Environmental audit for supplier ^a	2.32 (1.69)					–
Spreading risk to third party ^a	3.0 (1.46)					–

^aItem dropped because of low loadings or loading on two constructs.

Note: Total explained variation 76.35% with varimax orthogonal rotation.

Factor 1 involves long-term strategic initiatives to tackle environmental issues. It explains how a UK manufacturer has a planned approach to control environmental factors embedded in its business strategies.

Factor 2 involves the short-term tactical initiatives adopted by companies to develop, assess, and implement an environmental management system across the organization to tackle issues related to the natural environment.

Factor 3 reflects the pollution control aspect in environmental performance. A manufacturer uses such operational capabilities to reduce resource consumption, replace hazardous materials in the manufacturing process with greener substitutes, and recycle waste.

Factor 4 represents pollution prevention strategies for organizations. This involves practices leading to waste reduction through both proactive measures like pollution prevention, elimination of waste before production, and reactive measures like having specialized waste treatment facilities.

Factor 5 reflects supply chain coordination, which involves conformance by suppliers and contractors to environmental standards as specified by the manufacturer. This involves setting up environmental standards for suppliers and taking decisions on raw material sourcing using environmental criteria.

Table 3 Canonical correlations and loadings (estimation sample)

	<i>First canonical function</i>	<i>Second canonical function</i>
Canonical correlations	0.87	0.34
Bartlett test of residual correlations (Chi-square, df, <i>p</i> -value)	55.92, 6, 0.00	4.67, 2, 0.09
Canonical loading of independent variables		
Strategic environmental initiatives	0.93	−0.38
Tactical environmental initiatives	0.96	0.28
Redundancy indices	0.67	0.01
Canonical loading of dependent variables		
Pollution control	0.94	−0.16
Pollution prevention	0.60	0.75
Supply chain coordination	0.84	0.03
Redundancy indices	0.49	0.02

Note: Stewart–Love redundancy index for overall analysis is 0.51.

Stage 2: Canonical Correlation Analysis

Hair *et al.* (1998) suggests use of split-sample technique to test the validity of CCA results. Thus, in this study, we divided the sample size of 76 randomly into estimation sample (with size 41) and validation sample (with size 35). The results from both the samples are similar, therefore we report the results based on the combined sample.

Table 3 describes the results of the CCA. Magnitudes of canonical correlation coefficients as well as the redundancy indices for each pair of the linear composites of the variables measure the strength of association between each set of independent and dependent variables. Canonical correlation indicates the strength of relationship between the linear composites of independent and dependent variables, while redundancy index gives the variance in canonical variates (Hair *et al.*, 1998). For both the canonical functions, the canonical correlation coefficients are 0.87 and 0.34. The first canonical function is significant at 0.05 levels using Bartlett's chi-square test. However, the second function is insignificant. Therefore, we ignore the second function for predictive purposes and for drawing managerial implications from the results. For the first canonical function, the redundancy index for the independent variables is 0.67, which indicates that independent variables explain 67% of the variation in the three dependent variables. Similarly, environmental performance items explain 49% of the variance in the environmental initiative constructs. Thus, the choices of independent–dependent variables are significantly interrelated. The Stewart–Love canonical redundancy index for the overall analysis is 0.51, which is analogous to *R* squared statistic in multiple regressions (Hair *et al.*, 1998).

Canonical loadings measure the simple correlation between the variables and their respective canonical variates. As suggested by Hair *et al.* (1998), we interpret these canonical loadings to indicate the strength of relationships between the sets of dependent variables and independent variables in this study. For the first canonical function, in the independent variate, both variables have loading of more than 0.9. This suggests that both the organizational strategic and tactical initiatives highly represent the organization's environmental efforts. For the dependent variables (environmental performances), the canonical loadings for pollution control and supply chain coordination are very high. This indicates that environmental initiatives greatly influence these two outcome variables. The canonical loading for pollution prevention is 0.6, which exceeds the 0.30 level as suggested by Lambert and Durand (1975) as the minimum acceptable loading value. However, this indicates that pollution prevention (the strategic outcome) does not play a significant role (in comparison to the other performance constructs) on firm environmental policy. The positive loadings for all the five constructs signify a strong positive impact of the environmental initiatives on environmental performances.

Discussions, Contributions, and Conclusion

Our study has thus provided an interesting view of the relationship between environmental initiatives and environmental performance. While it agrees with previous similar studies in that there is statistically strong association between the two, our study provides more interesting insights to extend the results of these previous studies. We do this by distinguishing three distinct measures of environmental performance: Pollution control, pollution prevention, and supply chain coordination. Of the three, pollution prevention seems to be less well associated with environmental initiatives compared with the other two (pollution control and supply chain coordination). It has to be noted that the literature has highlighted the distinction between pollution control and pollution prevention. While the former involves short-term view in managing environmental performance, the latter involves a longer-term view (Klassen and Whybark, 1999; Nath and Ramanathan, 2016). Thus, our study shows that there is less support in UK manufacturing firms in taking longer-term view on environmental performance, and that these firms tend to take shorter term view when it comes to improving environmental performance using various environmental initiatives.

Contribution

This study contributes both to environmental management literature and to understand the environmental approaches adopted by the UK-based manufacturing firms. Earlier studies in environmental management literature (e.g., Montabon *et al.*, 2007; Berrone and Gomez-Mejia, 2009) often provide a contradicting and inconclusive association between environmental initiatives adopted by firms and their environmental performances. Based on a content analysis approach and in a multisector manufacturing setting, this study empirically demonstrates that environmental initiatives (strategic and tactical) have positive but varying levels of influence on the three environmental performance constructs (pollution prevention, pollution control, and supply chain coordination). This study thus empirically verifies the ambiguity (positive as well as negative) in relationships between environmental initiatives and performance stated in extant research and supports the “win-win” hypothesis (Porter and van der Linde, 1995).

The study also finds that UK manufacturing firms adopt environmental initiatives both to attain economic (short-term) or strategic (long-term) goals but the focus has been more on the short-term, compliance based, and reactive objectives rather than the long-term, proactive strategic ones. Thus, the study provides evidence to UK policy makers to design better legislation or added incentives to ensure UK firms adopt pollution prevention rather than pollution control environmental strategies.

Implications

The findings of this study conclude that the commitment of top management in the UK manufacturing firms in devising appropriate environmental initiatives trickles down to generate expected results in terms of environmental performances. All the canonical loadings are high; loadings for the two independent variables exceed 0.9 while loadings for dependent variables are also high except for pollution prevention. The loading is moderate (0.60) for pollution prevention indicating that top management’s environmental commitment may not have resulted in a long-term realization of waste control targets. This finding is not surprising as UK manufacturers are more concerned about rise in energy prices, landfill taxes; cost of dealing with hazardous wastes, thus a current immediacy of benefits is of primary concern to them. This is consistent with the findings of previous studies (like Dahlmann *et al.*, 2008; Ghobadian *et al.*, 1995) which characterize British firms as adopting short-term, risk avoidance attitudes towards environmental initiatives with cost reduction as primary motive. The most important managerial implication of our results is that it provides evidence in the UK context that operational level environmental targets can be realized with adequate strategic support and environmental management plans from the top management. However, the motivation to achieve the environmental targets is still economics driven. Given the growing importance of conformity to environmental regulations, and the changing landscape to incentives to comply with environment (like carbon trading programs), UK policy makers need to offer the right package of incentives to manufacturing firms to make them more environmentally proactive.

Introduction

The circular economy is the evolution of the linear business model in which products are manufactured from raw materials, then abandoned in landfills at the end of their useful life (Tecco *et al.*, 2016). In the circular business idea, product design is developed with the aim to repair, reuse or recycle the products at the end of their life cycle (World Economic Forum Mining & Metals Industry Partnership in collaboration with Accenture, 2014). The model is based on the idea of minimizing waste and their amount. In recent years, the construction sector has been the focus of the scientific community in terms of circular economy and emission reduction: construction and demolition waste (C&DW) accounts for 34.7% of total waste production in Europe as reported by Eurostat (see “Relevant Website section”). Thus, the interest of the policy makers and the scientific community to reduce the impact deriving from this waste stream is evident. In this regard, the European directive 2008/98/EC indicates that 70% of waste must be recycled by 2020. Currently, the best way to recycle construction and demolition waste is the production of recycled aggregates, to be mixed to concrete in order to build new structures (Colangelo *et al.*, 2015, 2017). Construction and demolition waste also represent a problem from the social point of view. It is clear if we think about the quantity of rubble as a result of disasters such as earthquakes, the impact of a quarry near urban areas or the volume occupied in landfills by inert materials, which forces to increase the storage space available in landfill, often going to affect the well-being of the community. In literature, there is a debate on the actual advantage of using recycled aggregates (Colangelo *et al.*, 2016; Colangelo and Cioffi, 2017). It arises from the need to use a greater quantity of cement, compared to a mixture containing only sand and gravel (natural aggregates), in order to ensure the same performance in terms of mechanical properties. The problem linked to cement is the fact that its production involves the emission of large quantities of CO₂. Mixtures with recycled aggregates have generally a lower density that allows to use a lower quantity of steel in the load-bearing structure of a building to guarantee the properties required by the legislation (World Steel Association, 2015). Regarding CO₂ emissions due to the production of cement, there is a debate in literature about a possible replacement of the traditional binder with a geopolymer, in order to reduce the global warming (Petrillo *et al.*, 2016; Turk *et al.*, 2015; Coppola *et al.*, 2018). It is clear that in achieving a circular economy model within the building sector, an approach that looks after the problem in its entirety is fundamental, analyzing all the possible advantages and disadvantages. This is fundamental in order to avoid that the achievement of the “zero waste” scenario requires a high price to pay: on one hand eliminating the production of natural aggregates, on the other hand increasing the production of cement. The most appropriate methodology to analyze the goodness of the recycling process for construction and demolition waste is the LCA. Using this approach, that takes into account all the phases of a building’s life cycle, it is possible to highlight the critical phases on which it is necessary to intervene to reduce environmental impacts.

In this study, the impacts related to the production of recycled aggregates for structural purposes is analyzed, considering different quantities of steel and cement depending on the use of recycled or natural aggregates within the mixture. In addition, the study investigates the sustainability of the mixture made with geopolymer binder in substitution of cement.

The aim of the present work is to contribute to the current indications given by the 2008/98/EC regulation on the recycling process of aggregates, as well as indicating possible ways to be followed in the near future. Unlike the papers found in literature, the impacts deriving from the production of the steel necessary for concrete reinforcement have also been taken into account. Furthermore, interesting considerations can be drawn about examined geopolymer mixtures.

The rest of the article is organized as follows: in Section “Overview on Life Cycle Approach of C&DW” materials and methods are described; Section “Materials and Methods” summarizes the main results of the environmental analysis; Section “Mixtures” discusses the mixtures prepared while the Section “Results” deals with the outcomes of the study. Finally, in Section “Conclusion” the main contribution of the work and future developments are analyzed.

Overview on Life Cycle Approach of C&DW

Since the 90s, many studies, have used the life cycle approach to analyze the impacts related to the production and use of concrete, as well as the reuse of demolition materials. These showed how the evolution of the C&DW study, using the LCA methodology, went hand in hand with the evolution of the reference legislation. Among these works, ten were taken as a reference for developing this study. The aforementioned studies are summarized in Table 1 that shows the object of the study, which ranges from the production of recycled aggregates to the production of the concrete mixture, the methods for defining the boundaries of the system and the functional unit adopted by the authors, in order to approve the best practices in the sector studies.

Table 1 State of art

In this work impact linked to the construction of the reinforced concrete structure of a building, with different types of concrete is analyzed: with recycled aggregates and natural aggregates. To make the analysis complete, impact of the construction of the aforementioned building with geopolymer concrete mixtures is assessed.

Materials and Methods

Goal and Scope

In this work a *from cradle to grave* approach has been used, i.e., the life cycle of the concrete mixture is taken into consideration starting from the extraction of raw materials up to the demolition, considering that our case study is about a building. Eight concrete mixtures were prepared with recycled and natural aggregates (with an amount of recycled aggregates ranging from 0% to 100%) and using both a traditional and a geopolymer binder. The SimaPro software was used according to ISO 14040-44 standards.

Functional Unit

In literature, we face with different types of functional units that are chosen with respect to the specific study. From [Table 1](#), it is clear how to move from one unit to another depending on the focus of the study. In the papers by Borghi and Blengini ([Blengini and Garbarino, 2010](#)) focused on the processes to which C&DW is subjected, one tonne of C&DW is certainly suitable for highlighting the criticality of the issue. Studies whose purpose to focus on the impact deriving from the production of aggregates, identify the functional unit as the tonne of aggregate produced. Again, as can be seen from [Table 1](#), it is possible to find LCA analyzes that take into account the use of aggregates in the production of concrete. They tend to take as a functional unit a cubic meter of concrete, often defining a particular class of mechanical resistance.

In this work the functional unit is represented by a cubic meter of reinforced concrete with mechanical resistance of 30 MPa: in this way in addition to taking into account the use of raw materials needed to the production of the building material, is also highlighted the contribution of steel to the sustainability of a building.

System Boundaries

The waste from construction and demolition, after the selective demolition, travel by road to the recycling plant, where they are treated; the secondary raw materials, output of the waste treatment plant, are then sent to the concrete mixing plant. The natural aggregates are transported from the quarries to the concrete mixing plant where concrete is produced and then sent to the construction site.

The impacts related to the construction, use and maintenance phase of the functional unit in a building have not been taken into account. This hypothesis is supported by numerous studies in the literature and it is assumed that the impacts are the same for all the mixtures analyzed. The analysis of the life cycle sees the demolition of the building as the final point; the steel of the demolished structure is sent to the recycling process and 15% of the inert materials is landfilled, following the hypothesis defined by [Colangelo et al. \(2018\)](#). Regarding to the remaining 85% of inert material, the process to which it is subjected has not been specified; this following the idea that in about sixty years, when the building will be subjected to partial or total demolition, the techniques of recovery could be reasonably changed.

The distances considered are the following:

- 30 km traveled by C&DW from the demolition site to the selected recycling plant.
- 20 km covered by recycled aggregates from the treatment plant to the concrete plant.
- 30 km from the cement production plant to the concrete mixing plant.
- 30 km from the sand and gravel quarries to the concrete mixing plant.
- 40 km from the concrete plant to the construction site.
- 300 km traveled by steel for the building's reinforcement. This is the approximately the distance that separates the steelworks of Taranto from a hypothetical construction site in the province of Naples.

In the case of geopolymer concrete production, the activities that lead to its production are very similar to those of mixtures with traditional binder except the production of the binder.

The distances considered are the following:

- 30 km traveled by C&DW from the demolition site to the selected recycling plant.
- 20 km covered by recycled aggregates from the treatment plant to the concrete plant.
- 100 km is the distance between the chemical plants that produce the precursors of the geopolymer and the concrete mixing plant.
- 30 km between the sand and gravel quarries to the concrete mixing plant.
- 40 km is the distance traveled by the concrete from the concrete plant to the construction site.
- 300 km are traveled by steel for the building's reinforcement and for the transport of the blast furnace slag from the steelworks to the concrete mixing plant.

Life Cycle Inventory

Data collection was carried out drawing on the numerous studies in the literature or, alternatively, using the data present in the eco-invent database. As an example below, we briefly elaborate some of them

- For the gravel natural aggregate, the ecoprofile is represented by the entry “Gravel, market for gravel, round {RoW} (RoW means for Rest of the World, while GLO means Global. They both represent activities which are considered to be an average valid for all countries in the world. They were chosen whenever specific data for the South of Italy could not be found)” in the ecoinvent 3 database.
- For recycled aggregates, the study by [Borghi et al. \(2018\)](#) has been considered. This study, supported by the administration of Lombardy region, has as its object the LCA of the current chain of disposal of demolition waste in Lombardy. [Borghi et al. \(2018\)](#) have quantified the consumption of electricity and fuel of fixed and mobile plants for the production of recycled aggregates. For the former has been estimated an electricity consumption of 1.74 kWh/t of recycled aggregate produced; 0.38 litres of diesel are used to produce one tonne of secondary raw material, and 0.03 kg of steel is used in the production of one tonne of recycled aggregate from a fixed plant.
- For the transportation, it was assumed that the materials travel on road, so the impact connected to the transported tonnes/km was assessed by referring to the item “Transport, freight, lorry 16–32 metric tonne”, EURO5 {GLO} | market for | Alloc Def, S “in the ecoinvent 3 database”.
- Electric energy; the data present in ecoinvent 3 have been used, in particular has been considered the medium voltage electricity produced in the Italian market.
- Also, data on the demolition of a building have been obtained from the study. In particular, 89.59 MJ of energy deriving from the combustion of diesel are needed to demolish 1 m³ of concrete.

Life Cycle Impact Assessment

In this work, the IMPACT 2002+ evaluation method was used to assess the impacts related to the production of concrete. The results of the characterization phase were interpreted.

Mixtures

In the present study, eight blends were analyzed. The four mixtures of concrete with recycled and natural aggregates are those suggested in the study.

Table 2 shows the composition and characteristics of these first 4 mixtures:

- Mixture with cement as binder and 0% recycled aggregates.
- Mixture with cement as binder and 25% recycled aggregates.
- Mixture with cement as binder and 50% recycled aggregates.
- Mixture with cement as binder and 100% recycled aggregates.

In **Table 3**, instead, the compositions and characteristics of the geopolymer mixtures under examination, prepared in the laboratory of the University of Naples “Parthenope”, are shown:

- Mixture with geopolymer binder and 0% recycled aggregates.
- Mixture with geopolymer binder and 25% recycled aggregates.
- Mixture with geopolymer binder and 50% recycled aggregates.
- Mixture with geopolymer binder and 100% recycled aggregates.

The amount of steel constituting the reinforcement was assumed to be 120 kg/m³ of concrete.

Results

The obtained results show a small improvement of the environmental profile as the percentage of aggregates increases; thus supporting the circular economy. In **Fig. 1** it is possible, in particular, to see the values assumed by the impact indicators after the

Table 2 Mix proportioning of concrete mixtures with Portland cement (wt%)

	<i>Traditional concrete</i>	<i>25% R.A. concrete</i>	<i>50% R.A. concrete</i>	<i>100% R.A. concrete</i>

Na ₂ SiO ₃ solution	5.90	5.95	6.06	6.91

Fig. 1 Characterization, comparison among 8 mixtures using IMPACT 2002+.

characterization phase. It is shown, for each impact category, with the value 100% the most impactful mixture, the other mixtures assume values between 0 and 100 by comparison with the higher one. From these first data it is possible to understand which categories are important to analyze in order to identify solutions that make the production of concrete more sustainable, as well as to identify areas where there is a large inequality between one solution and another one. Results seem to discourage the production of the geopolymer mixture.

Discussion

Thanks to the results of the present study it is possible to give an answer to the questions that have moved the research, as well as to identify possible future developments. The use of recycled aggregates is always preferable compared to the traditional solution: the use of a circular economy model represents an efficient strategy for the construction and demolition waste sector. It would be interesting to analyze the impact deriving from the use of recycled aggregates from a mobile plant in order to evaluate the potential advantage in logistical and social terms. Other categories, such as "Mineral Extraction", are mainly influenced by the materials constituting the steel rebars. In this study a fixed amount of steel was considered for each mixture, it would be interesting to quantify the impacts after the calculation of the effective quantity of steel needed in each mixture.

Conclusion

The problems related to the increase in construction and demolition waste, together with the desire to reduce the impacts deriving from the construction sector, have pushed this study to find a strategy to reduce the environmental impacts. After a careful literature analysis aimed at identifying the best practices of the LCA applied to the construction sector, it was decided to analyze the results of the characterization phase for each impact category. It was therefore possible to identify the best scenario to investigate, as well as to evaluate the effective validity of the application of the circular economy concept in the construction sector suggested by the European Directive 2008/98/EC. With the assumptions made in the present study, the solution consisting in concrete with 25% of recycled aggregates is the best in most of the selected environmental impact categories of the method IMPACT 2002+. Furthermore, all solutions with recycled aggregates are not more impacting than those having exclusively gravel in the mix design. Therefore, the recycling of concrete for the production of secondary raw materials is perfectly in line with the dictates of an efficient circular economy. Excluding the recycling, steel accounts for about 15% in two of the main categories of the IMPACT 2002+ method and about 30% in the “Respiratory Inorganics” category. Other categories, such as “Mineral Extraction”, are predominantly influenced by the material constituting the steel rebars. The values can change considerably applying one impact evaluation method rather than another. In this regard, efficiency could be increased generating a greater number of facilities of the “chain” that allows to obtain the concrete available at the construction site. It would be interesting to study what would happen in case of production of recycled aggregates of sufficient quality in a mobile plant, followed by a reuse on site; it would be also interesting to examine an already developed context where the distances to travel are shorter. As regards the possibility of using geopolymers, these represent an already valid alternative with regard to the reduction of “global warming”; however, the big impact in the other categories, connected to the production of sodium silicate and sodium hydroxide, represent an obstacle to their employment. The weak point of this study is represented by the absence of primary data: databases and data in literature have been used. The above perspectives indicate the importance of studying in detail the production process of geopolymer precursors in order to identify the critical issues: a possible reduction of the environmental load connected to the production of sodium silicate and sodium hydroxide would increase the employment of third-generation cements.

Local Food and Healthy Eating for Wholesome Life: Some Policy Considerations

Ishwari S Bisht, Shemrock Cameo, Haldwani, Uttarakhand, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

Wholesome life is a way to live in a manner that makes one feel whole and fulfilled every moment of one's life. The word *wholesome* is a condition, and in the present context, means the whole, sound, and perfect health of a person. Wholesome people are healthy, not only in body but also in mind and in spirit. According to the Bhagavadgita, the *gunas* (the primary qualities or modes of nature) are three in number: *Sattva*, *rajas*, and *tamas*. They exist in all, including humans, in various degrees of concentration and combination. They also exist in all objects and natural products. Hence, even the food that we eat is important if we want to cultivate good behavior. Food choices must be conducive to the cultivation of *sattva*, since *sattva* improves the vigor and the brilliance of the mind and the body. We are, however, ignorant of the fact that the food we eat plays a huge role in our ability to keep our physical, mental, emotional, psychological health, and overall well-being in balance.

Kuhnlein *et al.* (2009) rightly emphasize on dimensions of nature and culture that define a food system contributing to the whole health picture of the individual and the community, not only physical health but also the emotional, mental and spiritual aspects of health, healing and protection from disease. Kuhnlein *et al.* (2009) further assert that "indigenous people never separated food from medicine, depending upon which part of the plant is used, the season of the year and physiological condition of the person using the crop, the same plant can be consumed as food or medicine." Further sustainability of the environment happened to be one of the critical issues in the food acquisition and consumption of indigenous communities the world over (Demi, 2016).

Sadhguru Jaggi Vasudev, a yogi, a profound mystic, a visionary humanitarian, a prominent spiritual leader and author, and founder of the Isha Foundation, a nonprofit organization that offers Yoga programs around the world and involved in social outreach, education, and environmental initiatives, also asserts that the type of food we eat has a huge impact on our body. He says that "in yogic system there is a physical body and a mental body. There is an intelligence and memory running right across the body. People generally think the brain is everything just because it handles the thought process. And because of this separation of body and mind, a large number of people in the West are taking antidepressants at some point in their life."

Mental health is a major concern worldwide and India is not far behind in sharing this. If we evaluate developments in the field of mental health, the pace appears to be slow (Srivastava *et al.*, 2016). Dr. Brock Chisholm, the first Director-General of the World Health Organization, in 1954, had presciently declared that "without mental health there can be no true physical health" (Kolappa *et al.*, 2013). More than 75 years later, the scenario has not changed substantially. About 14% of the global burden of disease is attributed to neuropsychiatric disorders. The burden of mental disorders is likely to have been underestimated because of inadequate appreciation of the interplay between mental illness and other health disorders (Prince *et al.*, 2007). There remain considerable issues of priority-setting based on the burden of health problems and of addressing inequalities in relation to determinants and solutions for health problems.

We all are familiar with the age-old saying "you are what you eat" but are often ignorant of this profound notion in applying it to our life. It is an accepted fact that some foods are good and some are bad for us but beyond this level of understanding we do not know the deeper meaning of food we eat. As we eat habitually and not intentionally or consciously, we have become so disconnected from the natural world that we do not know what this food is doing in our body beyond the momentary taste sensation in the mouth.

It is common knowledge that all animals, except human beings, living in their natural environment are not overweight or suffer from any chronic illness as a result of their diet, as they have natural intelligence that drives their food choices and they know what to eat. We, therefore, need to change our food system because the solution for health is not necessarily healthcare, it is actually our food system. Addressing both together, that is, creating a mindful nation and changing the food system, is the answer.

We all are aware that modern life, in this technological age, is very stressful as many things are competing for our attention and we are living in a constant state of excitement. Meditation has been advocated as one way to find stillness and quieten the mind but it has been quite challenging to many of us. The food we eat has been considered to play an important role in our ability to reach that meditative state. Our nervous system and brain never allow us to transcend our body when certain nutrients are not present, or when we are in a state of *nutritional stress*.

Our bodies contain similar nutrients to the food we eat. Therefore, depending on what kind of food we are consuming and the contents of that food, we are affecting our nutrient levels and overall, our health. On average, the human body is 6% minerals, carbohydrates, and other nutrients; 16% fat; 16% protein; and 62% water. Of course these percentages vary for every individual person depending on diet and lifestyle.

As mentioned above, it is important to eat a wide variety of foods from the five food groups to ensure that we are consuming all the different nutrients that our body needs. Eating one type of food may supply us with excess of a particular nutrient, but our body will be lacking other vital nutrients only obtainable from different foods. We often don't think about the nutritional content

of our food, but need to do some research and find out what we're really putting in our body when we eat certain foods. "When it comes to food, ask the body with what kind of food it is really happy. Try different foods and see how your body feels after eating the food. If your body feels very agile, energetic and nice, that means the body is happy. If the body feels lethargic and needs to be pumped up with caffeine or nicotine to stay awake, the body is not happy" asserts Sadhguru. Awareness of the contents of our consumption is the first step in moving towards a healthier diet and therefore, a healthier body. If we eat large quantities of high-sugar foods, we can continuously tax our system and eventually cause problems that can affect our health forever, such as type 2 diabetes. It is important to make a habit of healthy eating. The more often we eat healthy, the easier it will be and the more we will start to enjoy healthy food over unhealthy food.

Although food is something that we need to sustain us physically, there's a spirituality to food that is being increasingly acknowledged by consumers. "To be healthy in mind, body and spirit, it's essential to be spiritually connected to the food we eat and to relish the experience of eating," said Heidi Demars, an organizer with the Bisman Food Co-op and 2013 Bush Fellow. "Understanding how to eat is just as important – sometimes even more so – as what to eat." For Peter Bolland, humanities department chair and professor of philosophy and humanities at the School of Social Science, Business, and Humanities at Southwestern College in Chula Vista, California, all food is sacrifice, because all food is gained by death.

Demars noted that issues with obesity in the United States, which have increased since the 1990s, also have made many consumers connect with food in a more meaningful way and seek healthier choices. As consumers, Demars said the biggest question is how we can be more mindful of where our food is coming from and the people that produce it. This also means considering the long-term consequences that might occur to our current food system.

In the present communication, therefore, some policy considerations based on the outcomes of a few exploratory case studies on local food system and culture conducted recently by the author (Bisht, 2018; Bisht *et al.*, 2017, 2018a,b) in the Uttarakhand Hills are outlined. The Uttarakhand Hills are primarily an agriculture-based society with a rich native food culture and traditions. Traditional farming landscapes and local farming communities provide us the opportunity to showcase how indigenous food sovereignty and food systems can contribute for overall health, well-being, and wholesome life of native communities. There has been an enhanced emphasis globally now on indigenous food sovereignty. The enhanced production and consumption of native food is being emphasized so that the poor have adequate access to good quality healthy food for a nutritionally adequate diet. This includes not only food rich in energy but also micronutrients, that is, the vitamins and minerals and other trace elements necessary for normal growth and development. The author's case studies' outcomes and similar studies on traditional food systems and indigenous food sovereignty documented elsewhere have been discussed here in context of policy considerations for overall health and well-being of the native communities. It is expected that this communication can serve as a guide to our planners and policy makers designing appropriate food, nutrition, and health related policies at the state, regional, national, and global levels for health care and overall well-being of the native communities.

Representative Agro-Ecologies of Uttarakhand Hills of India and the State of Household Nutrition and Health

Of the total geographical area of Uttarakhand State, about 86% is hills where subsistence agriculture is practiced, which directly or indirectly sustains about 50% of the population of the state. On the other hand, there is 14% plains area where improved agriculture is practiced and most of the food grains are produced here. Farming communities in hilly areas of Uttarakhand State traditionally grow diverse crops as polyculture. Most of these native crops and their traditional landraces/farmers' varieties form the "functional foods" to hill farming communities with nutraceutical properties and high nutritional value. Further, about 70%–80% of the population is still directly or indirectly engaged in agriculture and allied sectors.

The traditional hill agriculture is highly knowledge-based and farmer-led innovations are predominantly practiced. All farmer-led innovations are socioeconomic and are not of a technical nature. Uttarakhand also has a rich food culture and tradition. Three representative farming agro-ecologies in Uttarakhand Hills as outlined by Bisht *et al.* (2018a,b) include:

- (1) Small-scale crop-livestock mixed-farming systems representing about 70% cropped area under rain-fed farming. The farming situations could be characterized by high household food production and dietary diversity. In the mixed crop-livestock farming system of the hills, there still exists a dynamic relationship among Common Property Resources (CPRs), native crops, and livestock. The livestock substantially contributes to household cash income whereas the surplus crop produce, if any, is sold locally and contributes very little to the household cash economy. The farming communities largely rely on plant-based vegetarian food. The wild plant resources also form an important component of the household dietary diversity.
- (2) High elevation mountainous areas adjoining Tibet with a mix of nomadic pastoralism, some arable land, and wild harvesting including foraging and trading of medicinal herbs. Sheep and goat are the herded livestock. Level of household food production and dietary diversity is moderate. This system is representative of about 10% of the farming areas in hills of Uttarakhand. Livestock grazing is practiced throughout the mountain valleys, although at rates significantly lower since the Indo-China conflict of 1962. Largely because the loss of trade with Tibet, demand for livestock and agriculture products as well as other professions linked to trade and agriculture including wool crafting and freight shepherding has dropped considerably but still contributes a lot to the rural economy. Consumption of meat is relatively high. Additionally, the wild harvested food resources such as *Jambu* or *Faran*, *gandharini*, *kala* or *bhotia jeera*, etc., are contributing immensely to the household cash economy.

- (3) A few interspersed river valleys where improved agriculture under assured irrigation is practiced and rice-wheat or rice-potato is the predominant cropping pattern. Household food production and dietary diversity is very low. The livestock herding particularly rearing of goats is minimal with limited contribution of livestock to overall cash income of the households. The river valleys represent about 10% of the cropped area in Uttarakhand Hills. In the river valleys, there is greater contribution of agriculture produce to the household economy.

A comparative study of household production and dietary diversity of the different farming situations was carried out during 2016 from 20 niche sites representing the above stated three agro-ecologies of the Uttarakhand Hills. Greater household production and dietary diversity were recorded in traditional rain-fed, small-scale crop-livestock mixed-farming systems followed by mountainous valleys with nomadic pastoralists, and least in river valleys with improved agriculture (Bisht *et al.*, 2018a,b).

A nutrition transition was clearly evident in farming agro-ecologies of river valleys with the emergence of cash crop economies and impact of globalization in recent years. Enhanced use of improved crop varieties from formal seed system, synthetic fertilizers, and pesticides is commonly seen in these farming systems. About 70%–80% of the cropped area is planted with a few improved cultivars of rice, wheat, and potato bred by public and private sector institutions. The produce of improved cultivars is generally sold in markets for cash income. Relatively reduced access to indigenous food resources and increased access to energy dense foods are creating an “obesogenic” environment in river valley areas.

In spite of nutrition transition trends in many other parts of Uttarakhand, it is widely acknowledged that in the representative target regions rich in crop and livestock diversity and use of wild harvested foods, the food traditions are still prevailing in the life of rural households to a greater extent. This is indeed heartening that the traditional food habits are still playing a great role in contemporary food habits of the target communities; therefore, the possibility of reversing the trends in favor of dietary diversification from dietary simplification looks promising. It was found that the root cause of both malnutrition and overnutrition/obesity is inadequate or improper nutrients. Consumption of an appropriate portion of food rich in essential nutrients can eliminate both pandemics.

In a comparative study of the connection between household production and the food local communities consume, and the physical, emotional, and mental health of the three representative farming agro-ecologies of Uttarakhand Hills, a clear linkage could be established. The high production and dietary diversity of traditional farming areas with small-scale crop-livestock mixed farming recorded the least incidence of food-based noncommunicable diseases like hypertension, type 2 diabetes, certain cancers, and everything from Attention Deficit Disorder to bipolar diseases, and to depression. A critical analysis of the food choices of the native communities in such farming situations indicates that they largely depend on a plant-based vegetarian diet. The wild plant resources also form an important component of their dietary diversity (Bisht *et al.*, 2017, 2018a,b). The wild plant resources, generally consumed in live form, make the communities physically and mentally agile and active.

Such farming agro-ecologies, therefore, need to be protected and a food-based approach made a primary healthcare policy in such farming agro-ecologies at the state, regional, and national levels (Bisht, 2018). Further, the cash crop economies in hill farming need to be discouraged as they will lead to enhanced malnutrition and outmigration of the rural youth.

Policy Considerations for Traditional Farming Communities for Their Food, Nutrition, Livelihood Security, and Overall Well-Being

The exploratory study of the author on household production and dietary diversity of different representative farming situations in Uttarakhand State clearly indicated that high production and dietary diversity is linked with better community health and nutrition (Bisht *et al.*, 2018a). Further, the traditional farming innovations are sustainable in terms of food production and spirituality in food systems is deeply integrated. The following policy interventions for overall well-being of traditional hill farming communities may, therefore, be considered:

- *Initiatives and research interventions for a diverse production system*

It has been emphasized that better and balanced nutrition in the human diet depends not only on growing a diversity of crops but also on the diversity within the crops (Mouille *et al.*, 2010). The micronutrient superiority of landrace cultivars complemented with wild food resources in traditional hill farming has been revealed by our case study findings (Bisht *et al.*, 2017, 2018b). Past researches, for example, have shown substantial intervarietal differences, for example, for beta-carotene in sweet-potato cultivars and the pro-vitamin A carotenoid of banana cultivars (Burlingame *et al.*, 2009; Litaladio *et al.*, 2010). The protein content of rice cultivars has also been reported to range from 5% to 13% (Burlingame *et al.*, 2009; Kennedy and Burlingame, 2003). Intake of one variety rather than another can be the difference between micronutrient deficiency and micronutrient adequacy in traditional farming. The micronutrient superiority of some lesser-known cultivars and wild varieties over others has been confirmed by certain recent researches (Heywood, 2013; Bharucha and Pretty, 2010). Unfortunately, we lack detailed information about such diversity within most crops at the cultivar level and the role it plays in nutrition because of the general neglect by researchers/professionals (Burlingame *et al.*, 2009) and much of the evidence is anecdotal.

Coates *et al.* (2007) suggest that dietary diversity can be used as a proxy indicator for nutrient adequacy. Adequate human nutrition thus involves regular intake of a wide range of nutrients, some of which must be consumed on a frequent basis, even if in small quantities. We believe that the trend in nutrition transition can be slowed down and certain approaches are needed to move

the nutrition transition in a more positive direction. Suggested public health promotion strategies, policies, and intervention approaches, as outlined by Smith (2013) include (1) holistic integrated food and nutrition interventions, (2) addressing under- and overnutrition simultaneously, (3) involving communities in planning interventions using a bottom-up rather than top-down approach, and (4) focusing on diversification of diets rather than a reliance on fortified foods and supplementation where possible.

We therefore need more diversity deployed in any production systems rather than uniformity and monoculture as advocated by corporate agriculture.

- *Documenting the indigenous knowledge and innovations*

Kuhnlein *et al.* (2009) argued that “Indigenous peoples’ food systems contain treasures of knowledge from long-evolved cultures and patterns of living in local ecosystems.” Therefore, traditional food systems need to be documented so that policy makers know what is at stake by ruining an ecosystem, not only for the native peoples living there, but also for everyone. Our study clearly indicated that malnutrition is not the result of food scarcity but foods poor in essential nutrients. Although the problem of diminished food sovereignty and food insecurity is one that affects all people, not just indigenous communities, indigenous peoples are uniquely situated to offer solutions. Armed with ancient traditional knowledge and a deep connection to their lands, indigenous communities, and particularly indigenous women are developing projects and building networks to revitalize local food capacity and strengthen food sovereignty.

The native food culture of Uttarakhand Hills can be discussed here in greater detail based on local IK in the context of food, viz. spirituality, food security, harvesting regulations/restrictions, and reliance on locally available material as outlined by Bisht *et al.* (2018a,b). The predominantly crop-livestock small-scale mixed-farming systems of Uttarakhand Hills encourage farmer households to consume more traditional crops instead of animal flesh, except for the nomadic pastoralists of high mountainous regions who depend relatively more on animal products. In indigenous animal husbandry of Uttarakhand Hills, the livestock are mainly fed with crop by-products while substantive food is mainly reserved for human consumption. Such systems save humans from competing with livestock for food and ensuring food sufficiency. In contrast, industrial agriculture contributes to creating food insecurity through the use of whole grains and cereals as key components of animal feed (Demi, 2016). The transformation of US diets from high-calorie crop products to low-calorie meat, for example, has greater environmental consequences (Albritton, 2012), with meat production contributing disproportionately to greenhouse gas emissions (Carlsson-Kanyama and Gonzalez, 2009; United Nations Environmental Programme, 2012). Further, feeding farm animals on crop by-products and forage ensures production of lean meat that helps reduce fat-related complications and diseases (Bernard *et al.*, 2006, 2009; Demi, 2016).

In traditional hill farming, use of local readily available materials, for example, use of forest litter, animal waste, farmyard manure, etc., and avoidance of synthetic fertilizers, except in river valleys where modern agricultural practices are followed, ensure that safe organic foods are produced for human consumption. These practices intend to help improve human health and preserve the environment for future generations. Indigenous diets worldwide are varied, suited to local environments, and can counter malnutrition and disease. For many indigenous communities, their food systems are complex, self-sufficient, and deliver a very broad-based, nutritionally diverse diet. But the disruption of traditional lifestyles due to environmental degradation, and the introduction of processed foods, refined fats and oils, and simple carbohydrates, contributes to worsening health in indigenous populations and a decline in the production of nutrient-rich foodstuffs that could benefit all communities.

The indigenous knowledge and innovations, therefore, need to be properly documented and used to bring sustainability in production systems.

- *State support to indigenous food sovereignty movements and promoting community-supported agriculture*

The development of sustainable agriculture will require a more radical transformation of agriculture, one guided by the notion that ecological change in agriculture cannot be promoted without comparable changes in the social, political, cultural, and economic arenas that help determine agriculture. The organized peasant and indigenous-based agrarian movements – such as the international peasant movement La Vía Campesina and Brazil’s Landless Peasant Movement – have long advocated for genuine agrarian reforms to access and control land, water, and biodiversity that are of central importance for communities to meet growing food demands.

Moving toward a more socially just, economically viable, and environmentally sound agriculture will be the result of the coordinated action of emerging social movements in the rural sector in alliance with civil society organizations that are committed to supporting the goals of these farmers’ movements. As a result of constant political pressure from organized farmers and others, politicians will, it is hoped, become more responsive to developing policies that will enhance food sovereignty, preserve the natural resource base, and ensure social equity and economic agricultural viability.

Within the larger society in which they live, despite the wealth of knowledge rural indigenous people have of their local environment and food system, they often face vulnerabilities derived from extreme poverty, discrimination, and marginalization. It has been rightly argued that the emerging concept of food sovereignty emphasizes farmers’ access to land, seeds, and water while focusing on local autonomy, local markets, local production–consumption cycles, energy and technological sovereignty, and community level farmer-to-farmer networks (Altieri, 2009). The case study on household production and dietary diversity is expected to set the stage for the future research to demonstrate how these local foods contribute to food security, nutrition, and health. Our long-term objectives will be to address scientific issues, public health, and policy, with the

goal of influencing local, national, and international policies for environmental protection of indigenous peoples' land and food resources. In this way, communities can be encouraged to strengthen their use of local food and sustain knowledge of their local food systems for essential contributions to cultural protection, well-being, and health. Local biodiversity should be recognized as a significant contribution to a sustainable agriculture–food–nutrition strategy alongside other nutrition–agriculture interventions (Heywood, 2013).

Local biodiversity and ecosystem services play an essential role in the lives of communities throughout the developing world, by providing a social safety net for food, medicine, fiber, fuel wood, etc., that can act as a route out of poverty and a source of income generation and can prevent people from falling further into poverty or in extreme cases as an emergency lifeline through the provision of “famine food” (Roe *et al.*, 2010). It can also play a major part in addressing issues of malnutrition (Heywood, 2013).

It has also been rightly argued by those concerned with the global food sovereignty movement that it is the small-scale farmers that actually have control of the food system, of information, and of food culture as against the social perception in the Northern Hemisphere that the large food chains feed society (Patel, 2009). Facing this, in the entire world, and especially in the Northern Hemisphere of the United States, Canada, Europe, impressive associations of critical consumers, and producers are being developed. In France, for example, there are 3000 producer–consumer associations. In Canada and the United States, where there is a common problem of reduced numbers of farmers, there is an enormous demand from citizens to have control over what they eat, how it is produced, and who produces it. They are demanding a new type, a new model of farmer, one that isn't trained in a productivist model (Patel, 2009).

It is believed that one of the effects of producer–consumer associations is to support the new farmers, who are increasingly coming from urban areas. In Europe, for example, many farming men and women now make a living based on local markets. They have a much better chance of survival than those farmers who depend on the transnationals for their inputs and sales. This is a very clear reality. To overcome this, urban social movements must come together with rural movements to develop a new type of agriculture and training that dignifies the profession, to excite young people (Patel, 2009).

Food sovereignty advocates rightly argue that the antipoverty approach runs the risk of reducing the issue of hunger and malnutrition to a humanitarian problem for rich countries to solve, a position that is highly contested by countries and societies that have long depended on agriculture for the livelihood (Mazhar *et al.*, 2007). Wittman *et al.* (2010) defined food sovereignty as the right of nations and people to have control over their own food systems, including their own markets, production modes, food cultures, and environments. Food sovereignty works with the concept of self-sufficiency in food production, democracy, and diversity. Lack of appreciation of these complex issues explains in part the rising cases of chronic diseases such as obesity and hypertension associated with overeating in the midst of food insecurity (Martin, 2012).

We therefore need community-supported biodynamic agriculture so that the problem of malnutrition is addressed by making available fresh and healthy food at the consumer's doorsteps.

- *Promoting wild food resources as component of dietary diversity*

Dependence of local communities of Uttarakhand Hills on diverse plant resources including wild food resources ensures that the plant species are protected, and in this way an effective mechanism of sustainability that indigenous communities can employ to maintain a cosmic balance with the ecosystem could be duly showcased by a recent case study research (Bisht *et al.*, 2017, 2018a,b).

Use of wild plant food resources in traditional farming as a component of dietary diversity, therefore, needs to be encouraged and wild habitats and CPRs duly protected through enabling policy support.

- *Participatory approaches and cross-sectoral collaboration and advocacy agenda for food-based approach towards community nutrition and health*

To achieve sustainable reductions in undernutrition and other forms of malnutrition, national policies and programs must be complemented by effective community-based actions. A key dimension of this strategy is enabling households to maximize food security and nutrition with existing household resources, while also striving to increase such resources. This requires a process of effectively mobilizing communities and shifting from a centralized to a more decentralized approach, with wider participation on the part of the community. A number of activities that address problems of household food insecurity and the various forms of malnutrition are being undertaken by FAO in both urban and rural areas. An important focus is community empowerment, with appropriate support from various governmental agencies and civil society institutions. At the community level, targeted and coordinated efforts focusing on improving household food security, fostering people's participation and empowering women and marginal groups are needed to address local food and nutrition problems.

Progress in promoting and implementing food-based strategies to achieve sustainable improvements in micronutrient status has generally been slow. These strategies focus on improving access to and availability and consumption of vitamin- and mineral-rich foods. Benefits of such food-based strategies include not only improved intakes of specific nutrients but also improved overall diet and health status. Since 1985, FAO has participated actively in defining and implementing programs to reduce micronutrient malnutrition. FAO strongly supports the promotion of the production and consumption of micronutrient-rich foods as the sustainable solution to micronutrient deficiency problems. This activity clearly falls within the Organization's mandate and overall strategy, which emphasizes the relationship between nutrition and agriculture to ensure food security and to improve the health and nutritional status of all populations.

Agricultural biodiversity is important for food and nutritional security. It also acts as a safeguard against hunger, a source of nutrients for improved dietary diversity and quality, and strengthening local food systems and environmental sustainability.

A recent compilation by Fanzo *et al.* (2013) explores the current state of knowledge on the role of agricultural biodiversity in improving nutrition and food security. The book explores current strategies for improving nutrition and diets and identifies key research and implementation gaps that need to be addressed to successfully promote better use of agricultural biodiversity for rural and urban populations, and societies in transition.

One of the world's greatest challenges is to secure sufficient and healthy food for all, and to do so in an environmentally sustainable manner. While the complexity and underlying determinants of undernutrition have been well-understood for decades, the scaling of food and nutrition system approaches that combine sustainable agriculture aimed at improved diet diversity and livelihoods have been limited in their development and implementation. However, an integrated system approach to reduce hidden hunger could potentially serve as a sustainable opportunity.

Uttarakhand State has limited political commitment to nutrition-sensitive agriculture. With the current emphasis on nutrition, a window of opportunity exists to promote nutrition-sensitive cross-sectoral strategies. However, efforts to communicate nutrition-sensitive agriculture and food systems as the system approach that encompasses all underlying causes of malnutrition in their interrelatedness and complexity along the whole value chain must be significantly increased (Balz *et al.*, 2015). Such an understanding is especially needed for a sustainable development goal concerning nutrition such as eradicating malnutrition in all its forms through sustainable food systems. Nutrition-sensitive agriculture seems to be more of a term than a concept. To promote nutrition-sensitive agriculture, a systemic approach and true cross-sector collaboration are needed (Balz *et al.*, 2015).

Research strategies designed to codeliver economic, environmental, and health goals will need to draw on interdisciplinary collaborations to define priority research questions. They should include a range of environmental indicators and not just greenhouse gas emissions and they need to take into account differences in impacts (partly due to different production systems) between countries (Gill *et al.*, 2015). Food-based solutions to hunger, malnutrition, and poverty are of global concern and must be addressed if food and nutrition security is to be achieved in a sustainable manner (Thompson and Amoroso, 2014).

The rising cases of chronic illness such as cardiovascular diseases, diabetes, and certain cancers among native and urban communities across the globe have been attributed to moving away from traditional foods rich in fiber, fruits, vegetables, and leafy greens to foods high in fat, sugars, and salt (Bjerregaard, 2010; Delormier *et al.*, 2009). Nestle (2007) asserted that different cultures understand their relation to food differently. Whereas the goal of food and eating within many indigenous communities is a means of expressing culture, upholding traditions, and strengthening cultural knowledge about the world (Willow, 2005), the goal of conventional nutritional science research reduces foods to its biochemical properties and categorizes it according to chemical compounds (Lupton, 1996; Scrinis, 2012; Warde, 1997).

The small-scale ecological farming methods are the key to ensuring resilience to climate change in Himalayan agro-ecologies. They are based on enhancing diversity, thereby increasing options to respond to climate instability. There is a need to support these traditional systems to feed local communities and at the same time address the traditional food-based approach of community nutrition and health. A proactive alliance, collaboratively creating a research and advocacy agenda in support of agrobiodiversity and the revival of diverse local food systems and landscapes, will be needed between indigenous peoples, local communities, and their key allies within the broader framework of indigenous food sovereignty. There is a need to reassess existing food and nutrition-related health and agriculture policy and develop cross-sectoral implementation strategies on food security, nutrition, and health. Further, there is need of continuous policy advocacy activities to educate functionaries across different sectors. Developing food composition databases is vital for effective advocacy tools and critical for cross-sectoral policy and program development (Bisht, 2018).

The general ignorance of nature and use of nutrient-rich indigenous and traditional food resources over the years has resulted in these foods being left out of most nutritional strategies put in place to address food security and nutrition problems of the population. Beside research-oriented activities, advocacy is an important thrust area of local institutional collaboration. There is a strong need to enhance the knowledge base of policy and decision makers at the local, regional, and national level across agriculture, food, and public health sectors on traditional food and nutrition. Continuous policy advocacy activities in the form of workshops, round-table discussions, stakeholders' meetings, etc., need to be organized to educate various functionaries across different sectors. There is also a need to reassess existing food and nutrition-related health and agriculture policy at local, regional, and national levels, harmonize such policies, and develop cross-sectoral implementation strategies that would positively impact on food security, nutrition, and health of the native communities.

There is lack of credible data and information on the compositional attributes of traditional food resources, which has greatly hampered efforts to inform and educate the population on the nutritional and healthful attributes of these foods. Developing the food composition database will be vital for effective advocacy tools and critical for policy and program development across agriculture, food, nutrition, and health sectors.

- *Enhanced market access and value chain development for traditional food resources*

Traditional varieties of different crops not only have different genetic attributes than modern varieties, they also have several consumption characteristics such as taste, aroma, cooking quality, nutrition, etc. In part for this reason – and in part, by virtue of commitments to environmental values – there is scope for development of local and distant markets in which traditional varieties command a price premium. Labeling systems can assist in creating such markets (Mann, 2004; Bisht, 2018; Bisht *et al.*, 2014, 2018a).

Again, this could not only provide direct rewards to growers, but also help to raise public consciousness of the importance of diversity and the need for public policies to sustain it.

Further, enhanced marketability and making them easily available in local markets through proper processing/packaging can add value to local food resources and increase their value in household food choices and family diets. Markets can play an important role in mainstreaming local foods in household diets and integration on nutritional contribution of traditional food resources to the well-being of the rural poor in the region.

In many instances it may be difficult to secure stable markets for raw agricultural products. This is particularly the case for crops requiring processing before they can be used. In these cases it may be possible to enhance the benefits to farmers of local varieties by processing them for particular markets. Increasing benefits to farmers through processing is one of the more costly and time consuming options available to enhance on-farm conservation. Detailed economic research and sample pilot studies are usually necessary to establish whether an initiative can be profitable and sustainable. Processing plants may be capital-intensive. Moreover, developing an industry to supply an agricultural product is likely to require government permission and regulation. One advantage to this approach is that interventions to increase benefits to farmers through processing can provide a sustainable mechanism for economic development and (after an initial outlay) may require only minimal monitoring and maintenance.

Ragi, finger millet or *madua*; rice; local black-seeded soybean, *bhat*; *gahat* or horse gram, etc., from traditional hill farming areas have a greater potential for value chain development and other marketing interventions.

- *Integrating local nutrient-rich food in midday meal program in line with lessons learned from Brazilian experience on school feeding programs*

In line with the success of Brazil's school feeding program, the traditional and healthier eating habits of Uttarakhand Hills can also be rescued. Several local crops offer more fiber, more vitamin B, and complex carbohydrates. Through policy advocacy activities, the school students should be made familiar and comfortable with what they are eating.

Further, like the Brazilian program, a substantial amount of Ministry of Human Resource Development budget can be diverted to small holder farmers for local purchasing of native healthy food to school feeding programs (midday meal scheme). In Brazil, 40% of food served to students is from local farmers and processors. The Brazilian experience has proved that small agriculture can produce good quality processed products – the kind of value-added products that can make farming more profitable. The small farms were capable of producing quality and good, dignified products that could positively contribute to the Brazilian school feeding program.

(Is any country, in general, and traditional farming areas like Uttarakhand Hills, in particular, ready for the change?)

- *Policies that encourage part-time farming*

One should recognize that farming need not be an all-or-nothing occupational choice. In an exploratory study from traditional crop-livestock small-scale farming areas, it was revealed that a small fraction of households (10%) earn their livelihoods entirely from farming, about 50% households earn most of their cash income from farming, and 40% households derive most of their cash income from nonfarm sources. The expansion of nonfarm employment at the community level will never eliminate farming.

Traditional agriculture in Uttarakhand Hills is highly labor-intensive and often does not provide full-time employment year-round to the labor force involved. Women comprise about 50% of the family labor force involved in agricultural operations, and the village youth, the rural labor force, is often not predominantly engaged in agriculture. Many youths also see traditional agriculture as an activity not worth the effort. It used to be family labor mainly involved in agriculture operations in the past. Outmigration of family labor in search of off-farm jobs to urban areas now is adversely affecting agriculture in the region. Policies that help to generate part-time, off-farm employment opportunities at the community level in rural areas can, therefore, help sustain small farms. So can policies that promote agriculture-friendly tourism, thereby internalizing another positive externality often generated by small-farm landscapes including the scenic beauty of Uttarakhand Hills. In supporting small farms, such policies could help to sustain agricultural biodiversity, especially if accompanied by other policies that recognize and reward the social value of its in situ conservation.

The off-farm job opportunities at the community level can be weaving, milling, food processing, eco-tourism, etc. Mahatma Gandhi National Rural Employment Guarantee Act of India, as a concept, has been a welcome initiative in this direction though there is a need to address problems in its proper implementation.

- *Awards and intellectual property rights (IPR) protection of farmer-led innovations*

The Protection of Plant Varieties and Farmers' Rights Authority (PPV&FRA) of India has instituted several awards in form of cash prizes, viz. Plant Genome Savior Community Award, and Plant Genome Savior "Farmer Reward" and "Farmer Recognition" to communities and the farmers engaged in the conservation of genetic resources of crop landraces and wild relatives of crop plants and their improvement through selection and preservation and the material so selected and preserved has been used as donors of gene in varieties registrable under the PPV&FR Act, 2001. Similar awards have also been instituted by the National Biodiversity Authority and State Biodiversity Boards for biodiversity conservation.

Another important step would be to promote noneconomic rewards for the conservation of agricultural biodiversity in annual fairs at the community level to farmer households. Such recognition not only makes farmers feel good; it also helps to create public awareness of the need for policies to provide economic rewards. Documentation and facilitating on-the-spot registration of farmer's varieties will help address IPR protection and enhanced exchange of local diversity. As farmers of the

region often have limited economic incentives in cultivating local landraces, native crop biodiversity can be recognized as a significant contribution to a sustainable agriculture–food–nutrition strategy alongside improvements in agricultural productivity and other nutrition–agriculture interventions.

Conclusion

Food choices must be conducive for improving the vigor and the brilliance of our mind and the body. The food we eat plays a huge role in our ability to keep our physical, mental, emotional, psychological health, and overall well-being in balance. Traditional diets are considered a delicious roadmap to healthy eating. Rather than relying on highly processed foods that are stripped of their nutrients, traditional diets celebrate the abundance of the earth's offerings, highlighting seasonal and regional produce, hearty recipes, and the pleasures of the table. Today, people are more disconnected with how food is grown and cooked than ever before. Excess salt, sugar, and saturated fats added to foods have been linked with rising public health problems, and changing food habits have distanced us from our bodies' natural hunger and fullness cues.

Traditional food systems play a significant role in maintaining the well-being and health of native communities. The traditional food choices include enhanced consumption of fruits, vegetables, and whole grains. By embracing traditional diets we can rediscover the joy in eating, as traditional diets are a delicious and pleasant way of enjoying healthy food for the rest of our lives. It has been reported that the deterrent of traditional foods to Western diets has caused a rise in obesity, cardiovascular disease, diabetes, and other health issues have increased in the last decade because of the availability of unhealthy foods. These are the risks of globalization when it comes to health and diets. It damages and shifts the developmental, cultural, and behavioral norms of its society. It changes food preferences.

Changing food patterns can damage the good health of the society. There is, therefore, a need to reassess existing food and nutrition-related health and agriculture policy, and develop cross-sectoral implementation strategies on food security, nutrition, and health. Further, there is need of continuous policy advocacy activities to educate functionaries across different sectors.

Local Skills for Moveable Factories

Stephen Fox, VTT, Technical Research Centre of Finland, Espoo, Finland

© 2020 Elsevier Inc. All rights reserved.

Introduction

Moveable factories are a leapfrog technology. As mobile telephony and finance leapfrog over fixed infrastructure in telecommunications and banking, so mobile factories leapfrog over fixed industrial infrastructure in manufacturing. Lack of local production skills is no barrier to rapid deployment of moveable factories. This is because local skills for moveable factories can be instructed in a few days through on-the-job training. Rapid training is facilitated by engineering uncertainty out of production operations to be carried out with moveable factories.

Moveable Factories

The technical feasibility of production operations without industrial infrastructure is increased by the diversity and sophistication of manufacturing machines that are becoming small and light enough to fit into trucks, trailers, carry cases, etc. Operational practicality is increased by capability of moveable factories to carry their own energy generating equipment, such as solar panels, across rough terrain. Economic viability is increased by reduction in capital investment costs from not having to construct factory buildings, and reduction in variable operating costs through not having to operate factory buildings. Although manufacturing may still involve the consumption of some non-renewable resources, these improvements to feasibility, practicality and viability bring concomitant opportunities for increased ecological sustainability. For example, building smaller lighter manufacturing machines involves less consumption of non-renewable raw materials; the use of mobile renewable energy generation reduces expansion of fixed power grids deploying non-renewable energy sources; and reduced construction of factory buildings further reduces consumption of non-renewable materials. At the same time, moveable factories open up new opportunities for increasing social sustainability by providing production employment for local people (Fox, 2015).

Local Skills for Moveable Factories

Local skills for moveable factories are not dependent upon medieval skill training practices, such as long apprenticeships, or 19th Century practices, such as construction of fixed training centers in buildings. Rather, local skills for moveable factories can be instructed in a few days of on-the-job training: provided uncertainty is engineered out of production operations with moveable factories. This involves engineering production processes to be capable processes (Figs. 1 and 2). In other words, engineering production processes so they conform to the production specification within upper and lower specification limits. The fulfillment of end-user expectations depends upon production processes being capable from conversion of raw materials through to the final product (Oakland, 2007). Having set upper and lower specification limits, further refinement of production processes can be achieved by reducing situated entropy. In particular, where work is right-first-time, there is zero situated entropy. In other words, the expenditure of energy is focused upon productive work: rather than energy being dissipated in unproductive iterations of trial and error. Consider, for example, self-assembly furniture kits. Information is provided by the furniture kit components themselves that can only be put together one way.

Fig. 1 Process capability specifications define technologies and skills.

Fig. 2 Moveable factories together with product kits leapfrog over skill shortages.

Information is provided by the hand tools that will only fit connecting bolts etc., in one way. Information is provided by visual instructions that can only be read in one way. Where there is only one way that something can be done in a particular situation, there is zero situated entropy. Where there is zero situated entropy, there are no skill shortages where the work is situated. By contrast, the more ways there are of doing something, the higher the situated entropy and the larger the skills shortage (Fox and Kotelba, 2018).

Conclusions

Throughout the world, there are large regions of unmet demand and unemployed people. This pernicious combination leads to social unrest, rural exodus, over urbanization, and mass migrations. The persistent failure to address this global challenge is rooted in the fixation of policy makers on extending 19th Century industrialization and rooting the training of skills in medieval practices such as apprenticeships that last many years. Moveable factories leapfrog over lack of industrial infrastructure and lack of local production skills. By providing on-the-job training, moveable factories becoming moveable training factories as well as moveable production factories.

Mining Industry

Patrice Christmann, Krysmine, Sandillon, France

Introduction to the Global Mining Industry

Together with agriculture and cattle rearing, mining, the process of extracting minerals from nature to turn them into the ever-growing range of products and services that humans nowadays rely on, is one of the oldest human industries. Nowadays, this industry comprises a myriad of very diverse activities of any scale, from artisanal (frequently informal) activities (Data and knowledge on this specific part of the global mining activities, of major social importance in a number of developing countries is provided by website present in “Relevant Websites section” and not further discussed here, as it has a limited role in the global production of minerals and metals, except for tantalum), to large scale highly capitalistic and complex industrial operations. It produces the minerals and metals needed by the infrastructure and many of the goods and services we, as humans, rely on. Almost every person living on Earth is depending on mining activities, however to different degrees of intensity ([International Resource Panel, 2011, 2019](#)), as the minerals and metals use of a country depends on its economic development level.

Modern industrial mining comprises all the very diverse activities ([Fig. 1](#)) that are needed to:

- Find (‘explore’) mineral concentrations of potential economic value (stage 1 and 2 in [Fig. 1](#)).
- Develop new mining projects through the assessment of the economic, environmental and social feasibility of their exploitation (stages 3 through 6 in [Fig. 1](#)).
- Mine these concentrations, to extract their economically valuable part (stage 7 in [Fig. 1](#)).
- Process the extracted material(s) in order to obtain marketable products meeting well-defined specifications (part of stage 7 in [Fig. 1](#)). Processing can involve several distinct steps. In the case of metals production, it mostly requires the production of a concentrate of the metal bearing mineral(s) contained in the natural metal bearing mineral assemblages known as ores. The valuable metal content of ores is extremely variable: while Brazilian or Australian iron ores commonly contain over 60% Fe, Chilean copper ores contain only about 0.6% copper, in average, and gold ores frequently contain less than 1 gram per ton.

Data shown in red, is indicative

Fig. 1 Simplified outline of the principal stages of an industrial-scale mining project. Figures in red are estimates of the average investment needed for industrial scale mining projects, based on Canadian mining projects.

- Close mining and related operations at their end-of-life and transfer back land that was leased for mining operations to its original owners or the state. Mine closure includes the decommissioning of the existing installations and, in principle, environmental restoration in order to avoid negative post-mining impacts (stage 8 in [Fig. 1](#)).

The mining industry has many specificities that differentiate it from other industries:

- The location of mines is determined by geology. This makes mines immovable assets.
- The importance of the framework conditions that attract or deter investment in specific jurisdictions, such as the quality of the geological database, the stability of the taxation and of the regulatory framework. Every year a report by the Canadian Fraser Institute ([Stedman and Green, 2018](#)) evaluates these framework conditions for a large number of jurisdictions.
- Minerals and metals are commodities. The price of one ton of copper is the same whether it comes from a Chilean, an US or a Polish mine. Mining companies have little or no influence on minerals and metals prices. These reflect demand and supply balances that are very difficult to forecast as they depend on multiple factors with complex feedback loops. These factors include speculative anticipations, technology shifts that can impact on both the demand or supply side, the development of recycling, of substitution or public policies ([Wellmer and Hagelüken, 2015](#)). Due to the commodity nature of minerals and metals also means that companies operating according higher sustainability standards than their competitors can't sell their products at higher prices than their competitors operating according to lower standards.
- The cost of mineral exploration and of the different stages necessary up to the demonstration of the economic and, nowadays, environmental and social feasibility of a project. In case of large-scale projects this can require tens of millions \$US without any certitude to ever recover this investment from a profitable mining operation.
- The risky capital expenditure needed to commission a new industrial-scale mine. A Global Data Energy survey of 483 mining projects worldwide, either in construction or predicted to enter the construction stage by 2020 ("see Relevant Websites section", (accessed 22.12.18)), shows that the average initial capital expenditure of these projects is 524 M \$US per mine, with wide fluctuations around this average. The capital expenditure varies a lot from project to project, reflecting the specificity of each mining project such as:
 - Differing production capacities;
 - Varying degrees of vertical integration (some projects have their own smelter/refinery while many only have ore processing plants);
 - Technical complexity and infrastructure requirements (some places on Earth have no energy and water supplying infrastructure).

For the largest and most complex projects the initial capital expenditure needed to build the mine and its auxiliary facilities can exceed 10 billion \$US.

- The average lead time from the initial discovery of a mineral concentration of potential economic interest and the commissioning of the related mine ranges from one to several decades. Project lead times depends on the economic attractiveness of the individual projects, the framework conditions existing in the different jurisdictions, the complexity of individual projects and their initial capital expenditure requirements. This lead time tends to get longer and longer in a number of jurisdictions as authorities impose that multiple detailed studies be completed and reviewed before granting the mining permit. These studies may include environmental and social baseline and impact assessments, environmental management and mine closure plans. prior to the delivery of the mining lease and mining permit that a company will need to obtain prior of building a new mine.
- The range of risks that may impact on mining projects at any of their stages (2 through 7 in [Fig. 1](#)) is wide. These include political instability, changes in applicable legal and taxation conditions, difficulties in obtaining the social license to operate, downturns in minerals and metals prices to name but a few risk factors typical of mining activities.

[Fig. 1](#) represents the main stages of mining projects from the initial geological surveys needed to locate potentially mineralized areas until mine closure, with an indication in \$US of the average investment required to finance each stage. No figure is given for the "production stage" as, under normal circumstances this stage generates revenue, whereby a part of it will be used to finance the capital expenditure that may be needed during mine life, for instance to finance an extension of the operations. The yellow background color shows where the role of States is predominant, through their public institutions (Geological survey, Department of Mines, Environmental Agency ...) promoting and regulating the development of mining activities. The green background highlights the stages where the role of investors, which can be private or public, is preminent.

More information on above stages can be found in specialized literature (see "Further Reading" at the end of this article) and websites such as the Canadian Queen's University Mine Design Wiki (see "Relevant Websites section").

While in China, the State directly or indirectly controls the mining industry via, for instance, regional banks, elsewhere minerals and metals industry activities are rarely vertically integrated in a single company. Exploration and the development of new projects the exceptions are essentially carried out by junior exploration companies ([Schodde, 2017](#), states that in the Western world junior companies make 70% of all the discoveries). Many of them listed on the Canadian (Toronto) or Australian (Sidney) stock markets. In its latest annual report on global mineral exploration, [S&P Global Market Intelligence \(2019\)](#), one of the leading consultancies specialized in minerals and metals related intelligence, states that over 3000 such companies are active worldwide. Larger mining companies, mostly transnational companies having the expertise and the resources needed to manage complex industrial projects, frequently take over advanced (Projects at the prefeasibility or feasibility stage. For a detailed overview of the design stages of new mining projects see for instance: website provided in "Relevant Websites section") projects to raise the capital needed for their

commissioning and then to operate the resulting mine and its related installations. Metallurgy and the related metal refining activities, where needed, are quite frequently run by different companies than mining operations. Taking the iron value chain as an example, the list of the world ten largest steelmakers (see “Relevant Websites section”) and of the ten largest iron ore producers (see “Relevant Websites section”) have only one company in common.

Most minerals and metals are produced by large transnational companies, with the exception of sand and gravel, ornamental and precious stone or tantalum, which are widely produced by smaller scale companies, and in the case of tantalum from the Democratic Republic of Congo or Rwanda, artisanal mines. In 2017, the 10 largest iron ore miners produced 53% of the world production, the top ten aluminum metal producers had an output of 56% of the global production, for copper this ratio was 47% and for nickel it was 64.

Except for the production of construction minerals and of dimension stone which is very widespread across the world, mining is concentrated in a rather limited number of countries. According to data from Reichl *et al.* (2018) (Fig. 2) only 16 countries contributed by value to 1%, or more, of the total world production. Nowadays, China is the world largest producer of 40 different minerals metals, including aluminum, cement and steel. On the basis of their per capita income level as defined by the World Bank (see “Relevant Websites section”), 4 out of the 16 countries listed are high income countries, and 9 of them are upper middle-income countries. Many of these countries developed their economic wealth due to a long history of mining and derived industrial and economic development.

Historically, up to the end of the 20th Century, the largest companies active in mining or metallurgy/refining had their history and headquarters rooted in a few countries with an ancient mining and/or metallurgical history and advanced financial services, mainly Australia, Brazil, Canada, the United Kingdom and the United States. Since the beginning of the current millennium large Chinese companies, as well as some Indian companies, appear among the world leading mining and metallurgical companies, in line with the rapid development of East Asia as the current economic powerhouse. In as little as three decades (1988–2017) China became the world largest producer of 40 minerals and metals (Schodde, 2018), reflecting the government’s strategy to foster economic dominance of some markets of major importance to the global economy such as consumer electronics, electric cars, information and communication technologies, solar panels, windmills.

Several public free-of-charge sources provide minerals and metals production statistics and, for some, much broader information about the global mining industry:

- The United States Geological Survey (see “Relevant Websites section”) provides production statistics, in some cases back to 1900, global reserves data, annual average minerals and metals prices, as well as annual reviews of the global industry organized per single minerals and metals or per individual countries and additional analysis.
- The British Geological Survey (see “Relevant Websites section”) provides production statistics, as well as additional analysis.
- World Mining Data (see “Relevant Websites section”), provides production statistics as well as country level estimates of the values of their productions.
- The Indian Bureau of Mines: in addition to information and data on India’s minerals and metals industry and trade it also provides global production data as well as some country level information (see “Relevant Websites section”).

In addition, various national authorities, such as Geological Surveys, provide national data and information in their respective national languages.

Fig. 2 World largest minerals and/or metals producing countries, ranked by their 2016 production value of non-energy minerals and metals, expressed in % of the world production value (approx. 745 billion \$US), not including the value of construction materials production (clay, cement, dimension stone, gravel, sand). Reproduced from Reichl, C., Schatz, M., Zsack, G., 2018. World Mining Data 2018 – Statistical Handbook. Austrian Ministry for Sustainability and Tourism. p. 263. <http://www.wmc.org.pl/sites/default/files/WMD2018.pdf>.

Mining Industry Segmentation

The mining industry comprises a number of main segments, defined according to the marketable products produced:

- Construction minerals: bulk or processed materials (*e.g.*, cement, clay, concrete, dimension stone, sand and gravel).
- Metals (including iron and ferro-alloys, non-ferrous and precious metals).
- Industrial minerals and derived products (*e.g.*, bentonite, gypsum, potash, phosphoric acid obtained from phosphate, sulfur).
- Precious and semi-precious minerals (*e.g.*, amethyst, emerald, diamond, ruby, tourmaline, sapphire).
- Energy resources (coal, lignite, peat, oil, gas, thorium, uranium).

As know-how, technologies and markets differ, most companies tend to specialize in only one of these segments, or even in the production of just one mineral or metal.

While this segmentation is widely used to document and describe the global mining industry, there is no global consensus about the segmentation of this industry, and different terms are used, for instance “minor metals”, a widely used term lacking a solid, reliable definition. These are supposed to be metals produced in small quantities, mostly as by-products of “main” or “carrier” metals, that are not traded via one of the specialized metals trading Exchanges (London Metal Exchange, Shanghai Futures Exchanges, New York Mercantile Exchange). There are some minor metals that hardly fit to this definition, for instance manganese, whose annual production (16 Mt in 2017 according to the USGS) is larger than the production of lead (4.7 Mt) or zinc (12.6 Mt), both traded on above mentioned exchanges. Manganese also is not recovered as a by-product.

It took the 1997 6 bn \$ fraud known as the Bre-X scandal, to trigger the development of a series of national resources and reserves reporting standards, providing data traceability and much improved transparency of exploration projects, up to the completed feasibility study. The Bre-X scandal happened in absence of a clear, enforced, regulatory framework on resources and reserves reporting by exploration companies: a junior company could lure unsuspecting investors towards the development of an allegedly major gold discovery on the island of Borneo (Indonesia), that finally proved to be a hoax.

The most widely known standards are the Canadian National Instrument NI 43-101 and the Australian JORC Code. The development of the international coordination of the various standards is the scope of CRIRSCO (Committee for Mineral Reserves International Reporting Standards) (ICMM, 2013). The UN Economic Commission for Europe (UNECE) develops the United Nations Framework Classification for Resources (UNFC) (UNECE, 2009) as a voluntary international resources and reserves reporting framework. The development of a global consensus on the definitions of the terms used in relation with the mining industry remains a field where progress is needed.

Mining, One of the Oldest Human Industries and One of the Most Modern Ones

The two oldest currently known underground mining activities were for flintstone, used for the production of tools and to light fires, at Nazlet Sabaha in Egypt, dated 40,000 years BCE, and for iron oxide at the Lion Cavern in the Ngwenya Mountains of western Eswatini (formerly Swaziland), also dated about 40,000 years BCE (see “Relevant Websites section”). The red colored iron oxide was probably used after crushing and grinding for body adornment and rock art. The production of stone tools started much earlier, some 3.3 million years BCE, even predating the appearance of the genus *Homo* by more than a million years (Harmand *et al.*, 2015). For more than 3 million years our ancestors use of the mineral realm was limited to the ever more sophisticated use of stone.

In the long human history, the use of metals only developed quite recently during the period from 7000–4000 years BCE, in a vast region covering parts of Mesopotamia (nowadays parts of Iran, Iraq, Syria and Turkey), Cyprus and Bulgaria to the West. Gold and, more rarely copper, naturally existing in their pure metallic form were the first metals used to produce artifacts. The extraction of copper from its natural mineral assemblages, named ore, through simple metallurgical processes appears to have developed during the same time. As arsenic is not unfrequently present in copper ores, some hard alloy of arsenious copper could be obtained that served to produce the first metallic plowshares, a major step in the development of Mesopotamia as a cradle of civilization. It also served to produce military hardware such as lances, daggers and arrow heads, an early illustration of the dual use of many technologies.

During Antiquity mining and metallurgical activities became locally very important economic activities. The Laurion silver mines located about 60 km East of Athens were critical to the cultural might of Athens, the Las Medullas gold mining and the Rio Tinto lead, silver and gold mines (both nowadays located in Spain) or the tin mining in Cornwall (nowadays in the United Kingdom) were major sources of wealth in support of the development of the Roman Empire. The long-distance trade of small amounts of minerals and metals also started well before the current era: the trade of oxhide copper ingots around the Mediterranean basin is documented about 1600 BCE (Rice Jones, 2007), amber from the Baltic coastline was discovered in Egyptian graves dated about 1400 BCE and glass beads of Egyptian origin, dating from the same period were discovered in Denmark (Varberg *et al.*, 2015).

Table 1 compares the estimated annual production of metals produced at the times of Emperor Augustus Roman Empire (27 BCE–476 CE) with their annual production in 2016, showing the massive production development that happened since these ancient times. Despite these early developments the production of minerals remained very limited up to the 20th century. It took

Table 1 Comparison the estimated average annual metals production rate at the times of the Roman Empire with their 2016 production at mine level (metric tonnes of metals contained in the ore)

Metal	Roman Empire, Augustus Reign (27 BCE–14 CE)		2016 mine production	
	Annual production estimate (in metric tonnes)	Source	Annual production (in metric tonnes)	Source
Silver	200	Varberg <i>et al.</i> (2015)	27,000	United States Geological Survey (2018)
Copper	15,000	De Callatay (2006)	19,400,000	United States Geological Survey (2018)
Iron/pig Iron	82,500	De Callatay (2006)	1,150,000,000	United States Geological Survey (2018)
Lead	80,000	De Callatay (2006)	4,820,000	United States Geological Survey (2018)
Gold	6	Varberg <i>et al.</i> (2015)	3100	United States Geological Survey (2018)

the many major discoveries made in engineering, in physics and in chemistry as well as the development of modern project management practices, particularly throughout the 19th and 20th centuries, to make modern mining and metallurgy possible. Before this industrial revolution mining techniques remained for centuries those described in [Al Hamdani's \(about 940\)](#) and [Agricolae \(1556\)](#) classical text books on mining and metallurgy.

Some of the landmark innovations that led to development of the modern mining industry are Newcomen's steam machine (1712), commercial electricity production (1870), dynamite (1866), ore minerals concentration by flotation (1886), and the numerous metallurgical and refining processes still used nowadays to produce aluminum (Bayer process for the production of alumina, 1888; Hall-Heroult process for the production of aluminum, 1886), steel (Bessemer process for the production of steel, 1856), copper (Outokumpu's flash smelting process, 1947). The continuous development of information and communication technologies that was triggered by the discoveries of the transistor (1947) and of the integrated circuit (1959) has also much contributed to the development of mining, ore processing and metallurgical technologies.

The development of ever larger bulk carrying ships after World War II, with the largest current vessels (the Brazilian Valemax vessels, Vale being a Brazilian iron ore producer) having a capacity of 400,000 t deadweight, was a major driver of the global trade of minerals and metals observed after World War II. While in 1950, Australia and Brazil respectively produced 2.4 and 1.9 Mt iron ore ([Melcher and Forbes, 1950](#)), in 2017 they respectively produced 880 and 440 Mt (A respective production rise of about 37,000% and 23,000%). The production of both countries is widely exported, essentially to China.

Innovations, as well the development of the mastery of large-scale industrial mass production during the first part of this century and around World War II (WWII) led to the massive development of the minerals and metals production recorded since the end of WWII ([Fig. 3](#)). While, within the 1927–2016 period (90 years) the human population rose by a factor of 275%, from 2 to 7.5 bn people, the cumulated tonnage of the minerals and metals represented grew by a factor of nearly 3200%. This highlights the massive development of material intensity happened since the 1950s, essentially in developed countries, leading to the development of large per capita stocks in society, with large differences between developed and developing countries ([International Resource Panel, 2011](#)).

After World War II, several European countries, as well as Australia, Canada, Japan, New Zealand, South Korea and the USA witnessed rapid economic growth, fueled by the need for reconstruction and rising living standards driving a rapid rise of the demand for minerals and metals until the two successive energy shocks of 1973 and 1979. Afterwards, their growth continued but at a reduced rate, as the demand for new infrastructure reduced and consumer goods became more resource efficient. A new, intense, demand for minerals and metals developed from 2002 onwards, due to the extremely rapid development of the Chinese economy. The 2008 economic crisis only temporarily reduced the demand for ever more minerals and metals.

The technologies, and the related skills, equipment and capital investment, needed nowadays by the mining industry are extremely diverse. They range from simple manual digging of galleries with basic tools such as digger's spikes, shovels, hammers, chisels widely used in informal artisanal mining up to advanced heavy and complex machinery that are increasingly embedding sensors, and complex functions such as 3D modeling of ore deposits and mine planning, preventive maintenance, real-time process and cost control or remote wireless/automated operation of mine or haulage equipment.

[Fig. 4](#) shows the development of the world production from 1927 to 2016, expressed in metric tonnes, of the same metals and minerals shown than those shown in [Fig. 3](#). This time the 1927 production is expressed as a basis level of 100, common to all selected minerals and metals. It shows that in just ninety years the production of aluminum grew by a factor of over 250 times the 1927 production, that the production of cement, chrome and nickel grew by factors in the 60–70 range, while copper, iron, manganese, phosphate, potash and zinc productions grew by factors comprised between 8 and 25.

The continued growth of the demand for minerals and metals observed since WWII is likely to continue over the coming decades ([Christmann, 2018](#); [Elshkaki *et al.*, 2018](#)), driven by demographic growth, the rapid development of the global middle-middle class ([Kharas, 2017](#)) and the continued urbanization of the world population ([United Nations, 2018](#)). The transition towards the use of low-carbon energy production to combat climate change will further stimulate the demand for several minerals and metals such as aluminum, cement and concrete, copper, steel and some rarer metals needed, to build wind and solar energy based production, storage and transportation capacities. The deployment of electric vehicles needed to improve urban air quality

Fig. 3 Production from 1927 to 2016, in billion metric tonnes, of a selection of widely used minerals and metals. Data from Kelly, T.D., Matos, G.R., 2018. Historical statistics for mineral and material commodities in the United States. United States Geological Survey. Data Series 140 Reston, Virginia, USA. Available at: <http://minerals.usgs.gov/minerals/pubs/historical-statistics/> for all data points, except for the 2012–2016 chromium production, taken from Reichl, C., Schatz, M., Zsack, G., 2018. World Mining Data 2018 – Statistical Handbook. Austrian Ministry for Sustainability and Tourism. p. 263. <http://www.wmc.org.pl/sites/default/files/WMD2018.pdf>, and for the other 2016 production data from U.S. Geological Survey, 2018. Mineral commodity summaries 2018. U.S. Geological Survey, p. 200. Available at: [doi:10.3133/70194932](https://doi.org/10.3133/70194932).

and the growing use of desalinated sea water to supply water to regions where surface and/or groundwater are scarce will also contribute to stimulate the future demand for more minerals and metals (Arrobas *et al.*, 2017; International Energy Agency, 2015; Moss *et al.*, 2013; OECD, 2018).

Sustainability Challenges: The Need for a Global Mineral Resources Governance Based on a Sustainable Development License to Operate (SDLO)

Despite the progress in minerals and metals recycling, recycling rates of many metals remain very low (Fig. 5, International Resource Panel, 2011) for a wide range of metals, especially the rarer ones used in small quantities in electric appliances, electronics, car or aircraft construction. In many of these end-uses they are difficult to economically recycle (International Resource Panel, 2013a) as products have not been conceived in view of the end-of-life recycling of the minerals and metals they contain, or because the prices of primary minerals or metals are too low and recycling technologies too complex to make them economically profitable. Another limit to recycling is the long use phase of some metals in a context of a continuing exponential growth of the demand: aluminum, copper and steel based products can have use phases of many decades, meaning that even if 100% of the corresponding stock would be recycled at the end-of-life of these products (rails, electric generation and transmission infrastructure, built infrastructure, aircraft ...) the recycled flow would only partly meet the demand.

The production of minerals and metals has important environmental impacts, both at their production sites, and globally through global greenhouse gas (GHG) emissions and, in some cases mercury emissions (International Resource Panel, 2013b; Kesler and Simon, 2015; United Nations Environment, 2013). These impacts are extremely variable, depending on the nature of the minerals or ore mined, on the processes used for mining, mineral processing and metallurgy/refining in the case of the production of metals. Impacts also depend on the energy sources used, coal being the most problematic, as well as on local environmental factors, on the governance of the operating companies, on the quality of the applicable local regulatory framework and of its effective implementation.

Fig. 4 Production growth of the same selection of minerals and metals than in Fig. 3, over the 1927–2016 period. Basis 100 in 1927 common to all minerals and metals. Data from Kelly, T.D., Matos, G.R., 2018. Historical statistics for mineral and material commodities in the United States. United States Geological Survey Data Series. 140 Reston, Virginia, USA. Available at: <http://minerals.usgs.gov/minerals/pubs/historical-statistics/> for all data points, except for the 2012–2016 chromium production, taken from Reichl, C., Schatz, M., Zsack, G., 2018. World Mining Data 2018 – Statistical Handbook. Austrian Ministry for Sustainability and Tourism. p. 263. <http://www.wmc.org.pl/sites/default/files/WMD2018.pdf>, and for the other 2016 production data from U.S. Geological Survey, 2018. Mineral commodity summaries 2018: U.S. Geological Survey, p. 200. Available at: [doi:10.3133/70194932](https://doi.org/10.3133/70194932).

In addition of a mineral resource, the production of minerals and metals requires different inputs, essentially energy (as electrical power, fuels and explosives), water and a wide range of chemicals that may be needed for mineral processing, metallurgy and refining. The OECD (2018) estimates that the production of the most common metals (aluminum, copper, iron, lead, manganese, nickel and zinc) is the cause of 7% of the current GHG emissions, while concrete is the cause of an additional 9%. By 2060 they could respectively represent 9% and 12% of the global GHG emissions. In Chile, the world largest copper producer (about 28% of the 2017 world copper production) it took an average of 94,000 litres of water per ton of copper produced. Water can be an extremely scarce resource in very dry regions, such as the northern part of Chile where most of the very large mines are located.

Emissions of GHG and of other gases such as sulfur and nitrogen oxides, vaporized metals or particulate matter can all happen during the production of minerals. The production of minerals and metals can also generate enormous amounts of residual solid waste, especially of ore processing tailings, a sand like material that is the uneconomic part of the original ore after the recovery of the valuable minerals. In addition to chemical residues, tailings can contain residual metal bearing minerals either because processes used to recover these minerals never have a 100% efficiency or because these metals are in minerals that were not considered as economic to recover. From there metallic ions may be leached out and form chemical compounds that can be harmful to humans and/or the environment. The issues can be particularly problematic in the case of low grade ores that contain a range of by-products metals that remain in tailings or metallurgical slag. In this context copper and gold ores can be of particular concern. Gold ores generally have grades of only a few grams gold per ton, meaning that 99.99% of the extracted ore will become tailings. In the case of Chilean copper ore, the average grade is about 0.6% Cu, meaning that 99.4% of the extracted ore will become tailings. In both cases these tailings may contain arsenic, cadmium, lead, mercury selenium and tellurium which can migrate into the environment.

The impacts of past mining activities can last for centuries after the closure of a given mine. The migration of harmful chemical compounds into surface or groundwater, soil contamination, wind dissemination of contaminated dust, and/or land subsidence due to the collapse of underground cavities resulting from mining activities can be cause of long-lasting harm. These impacts can be aggravated by local natural conditions such as important seismic and/or volcanic activity and/or landslides. The mitigation of

Fig. 5 Recycling rates of 60 elements, mostly metals, from end-of-life products. Source: International Resource Panel (IRP), 2011. Recycling rates of metals – A status report (it is its Fig. 4). A report of the working group on the global metal flows to the UNEP international resource panel. In: Graedel, T.E., Allwood, J., Birat, J.-P., *et al.* (Eds.), UNEP. Nairobi, Kenya. http://www.unep.org/resourcepanel/Portals/24102/PDFs/Metals_Recycling_Rates_110412-1.pdf.

these impacts and the clean-up of derelict mining sites can be very costly to generations of taxpayers that did not benefit from the past mining activities (Indian and Northern Affairs Canada, 2010; Lysyk, 2015). It is only since some years that the cost of future mine closure and of site remediation are integrated in the feasibility studies and properly provisioned for by some companies.

Raising awareness of populations about the potential impacts of mining activities can lead to conflicts that, in the worst case, have a high human toll (Hammond, 2012) or simply ruin an investment, such as the recent Minas Congas conflict in Peru. New mining projects are confronted with a rising opposition to new large-scale mining projects and with the demand of various government for ever more detailed environmental impact assessments. At the same time the demand for minerals is growing and, in total contradiction, the ever growing part of the richer part of the world population demands more and more minerals and metals.

Despite its impacts, the mining industry is vital to humankind and it contributes in many ways to the United Nations Sustainable Development Goals (UN SDGs) (Columbia Center on Sustainable Investment, 2016).

To further strengthen the positive linkages between the minerals and metals industry and the UN SDGs requires:

- A strong, publicly verifiable, indicators based, commitment of individual companies to these goals.
- Market recognition of good corporate practice.
- Effective regulatory frameworks, including for international trade, enshrining sustainable environmental and social conditions.

Meeting the challenges of the 21st century requires the definition of a Sustainable Development License to Operate, based on:

- The recognition and verifiable involvement by mining companies and governments of populations living in the vicinity of future mining, ore processing and/or metallurgical projects. Local populations are an important stakeholder that needs to be associated to the design and planning of new projects from their early stage (exploration). Local populations need to be convinced about the sustainable benefits that will result for them from the project, and how the ecosystemic services they depend on for their livelihoods will be protected.
- Transparency and publicity of projects from their earliest planning stages (stages 2–5 in Fig. 1). In this context the Canadian regulatory obligation, known as National instrument NI 43-101 (Canadian Institute of Mining, Metallurgy and Petroleum, 2016), that makes it compulsory for any company listed on a Canadian stock market to report and publicly disclose its exploration and mine planning activities in a specified format, should be considered as good practice.

- Allocation of mining permits on the basis of public feasibility studies. For larger projects and/or projects liable to generate significant environmental and/or social impacts, the feasibility study needs to comprise environmental and social baseline studies and impact assessments, auditable environmental management strategies and plans, a social development plan, provisions for an annual sustainability reporting, a mine closure and a post closure monitoring and management plan with the guarantees necessary for their financing by the future mining activities;
- Quadruple (economic, environmental, governance and social) public sustainability reporting of producing mines, ore processing and metallurgical/ refining facilities with production above a given threshold or liable to produce significant impacts. The current best practice in this respect is reporting using the mines and metals industry reporting standards developed by the [Global Reporting Initiative \(2013\)](#) and the ISO 26000 standard.

These regulatory obligations need to be adjusted for smaller projects and those that have demonstrably limited environmental and social impacts.

However regulatory frameworks, and especially the public capacity to effectively implement them, remain weak in some countries due to a number of factors ([World Bank, 2017](#)) with regulatory frameworks not properly integrating sustainable development issues and/or institutions such as Geological Surveys, Mining Directorates and Environmental Departments not being properly supported, in terms of budgetary, human and technical resources to properly develop and enforce pro-sustainable development regulatory frameworks.

In addition, as stated by [Ali et al. \(2017\)](#) "*International environmental policy is currently missing the resource dimension for meeting both ecological and development targets.*". Unfortunately, instead of working on the development of the sustainability based global playing field, based on the SDLO, with transparency and quadruple bottom-line accountability, there is a growing trend towards resource nationalism. China, as the world largest producer of 40 minerals and metals, needs to play a leading role in fostering the transparency and the quadruple bottomline accountability of the global mines and metals industry, including for their operations outside of China. So far its efforts remain very modest.

The issues ahead call for much more international cooperation, to set up the needed global governance framework needed to address them. The creation of an International Mineral Raw Materials Agency based on the model used to develop the International Energy Agency (See "Relevant Websites section") could be an important step in the right direction. From a sustainability perspective there would also be much scope for a decommodification of minerals and metals, whereby economic incentives should be given to minerals and metals produced by companies offering verifiable high-level sustainability performance.

Introduction

Heavy metal contamination has become a serious problem for all over the world due to indiscriminate use of anthropogenic activities. Heavy metals include a heterogeneous group of elements having relatively high density ($< 5 \text{ g/cm}^3$) and atomic weight. Heavy metals naturally exist in the earth, but their concentration is continuously increases due to rapid industrial and human activities (Nagajyoti *et al.*, 2010). Heavy metals are non-degradable due to their complex chemical composition and thus persist into the environment for years and years.

Industrial activities such as smelting, tanning and mining, pulping, dyeing, food processing, electroplating, chemical manufacturing are the major point sources for the metal contamination into the environment. These all industries are highly water consuming industries i.e., these are using a huge amount of water for their processing and after processing them, also release water as in the form of effluent or wastewater (Mishra and Bharagava, 2016; Dixit *et al.*, 2015). The wastewater released from such industries containing a rich amount of pollutant both organic and inorganic and metals. Most of the metal ions such as mercury, cadmium, chromium, lead, and nickel are highly toxic in nature and tend to accumulate in living organisms causing carcinogenic, genotoxic, mutagenic and teratogenic disabilities (Yadav *et al.*, 2017). Heavy metals are become an issue of public health concern about environmental contamination and pollution. Thus, it is very essential to remove or reduce heavy metal contamination from the environment in order to protect the ecological balance of between aquatic and terrestrial ecosystems. According to World health Organization (WHO) every year 15,000 metric tons of cadmium is added to oceans.

The negative effects of metal pollution on the environment and human health, becomes an issue of serious matter of concern, which needs an alternative methods for excavation and incineration for the clean-up of metal contaminated sites resulted in the emergent of advanced and environment friendly applications of bioremediation practices.

Rhizoremediation is one of the best, widely accepted, cost effective bioremediation technique that subsequently focus on the application of rhizospheric microorganism and interaction with plant under stresses environment (Hryniewicz and Baum, 2011). Under metal contaminated environment, the application of rhizospheric microorganisms can enormous, since they are able to increase the tolerance level of plants against higher concentrations of toxic metals, enhances plant growth and accelerated the accumulation and biodegradation of toxic metals and other pollutants to in a more efficient way. Hence, here in this article, we will discuss the burning problem of heavy metal pollution originating from increased industrialization and urbanization and its management practices by using metal and microbes interactions in an ecofriendly manner.

Metal Contamination in Environment & its Sources

There are two main routes of heavy metals into the environment the first one is natural weathering of parent rock material and second through anthropogenic activities. Natural sources include paedogenesis and weathering of minerals, volcanic activities, and erosion. Whereas, anthropogenic sources includes various industrial and domestic activities such as smelting, electroplating, tanning, mining, use of chemical fertilizers and pesticides in agricultural practices, paints, pigments and dyes in textile and food processing industries (Gadd, 2010). Regular practices of mining procedures from coal mines for the extraction of metals such as Cd, As, Fe, Cr, Pb etc., are mainly responsible for the direct contamination of these metals into the nearby soil areas. Paint and electroplating based industries contributes for the Pb and Cd contamination into the environment. Tanning industries are the biggest source of Cr contamination because of its chrome tanning process using chromium salts (Bharagava and Mishra, 2018).

The widespread use of chemical fertilizers in agricultural practices for crop yielding donates substantial amounts of various toxic metals like Mo, Fe, Zn, Ni and Pb to the soil in the form of macro and micronutrient elements. However, these metals play an essential role in the metabolic and enzymatic processes of plant growth and soil fertility, but their excess concentration in soil results in toxic detrimental effect on plants soil and on humans as well (Reeves and Baker, 2000). The untreated wastewater and sludge emanating from such industries is the major source of metal pollution in water bodies and land areas. Once the metals enters into the water or soil systems above their permissible limit, becomes toxic in nature and are able to cause serious various complications in human, plants, animals as well as in aquatic and terrestrial biota (Zhang *et al.*, 2011). The heavy metals become a

major threat to the soil and water systems because of their extensive use and demand in industrial sectors. The heavy metals released from industrial activities, possess harmful effects which directly affect the biodiversity of any ecosystem (Arao *et al.*, 2010).

Toxicity of Metals in Environment & Living Beings

Metals play a vital role as a catalyst, co-factor and or in associated form in enzymatic and non-enzymatic reactions in biological processes of any living organism. However, their higher dose could be lethal for any living being and ecosystem as well. Many heavy metals such as calcium, cobalt, nickel, copper, iron, potassium, magnesium, sodium, zinc are essential and required in a trace amount as micronutrients and therefore are called “trace metals” or “trace element” (Wuana and Okieimen, 2011). Trace metals actively take part in redox-processes and enzymatic processes for proper functioning of metabolic reactions. Some metals like aluminum, silver, lead, and mercury have no defined role in biological systems so they are known as non-essential metals and these may be considered potentially more toxic than trace metals.

However, the higher concentration of both essential and non-essential heavy metal is extremely toxic and lethal for humans, animals and plants as well. As, which is predominantly used as coloring in textiles, is conspicuously lethal, causing cancer and numerous other health disorders like skin damage, and circulatory problems (Scragg, 2006; Yadav *et al.*, 2017). Cd is ranked as the sixth most toxic metal which severely affects metabolic rate of Ca^{+2} ion resulting in low muscle power, bone fractures, cartilage disorders, kidney damage (ATSDR, 2008). It also causes indirect oxidative stress and nutrient deficiency in plants too by inhibiting enzymatic reaction (Irfan *et al.*, 2013; Giaginis *et al.*, 2006). Pb is highly toxic and hazardous metal, when enters into the human body causes infertility and memory dysfunction. It prominently plays a role in the severe Pb-poisoning in infants and young children, which leads to even death also by altering cell signaling, protein folding and inhibitory effects on di and monovalent cations (Monterroso *et al.*, 2003; Flora *et al.*, 2007). Pb toxicity in plants results in membrane damage, disruption of photosynthetic cycle and production of reactive oxygen species (ROS), has detrimental effect on plant (Najeeb *et al.*, 2014).

Hg is a well-known hazardous and exceedingly poisonous, causing neurotoxicity, gastrointestinal toxicity and nephrotoxicity. It also results in protein damaging, cellular dysfunction, lipid peroxidation and accumulation of neurotoxic molecules (Tchounwou *et al.*, 2003; Patrick, 2002). Chromium is well reported extremely toxic, priority pollutant, designated as “Human carcinogen” metal by International Association of Research Cancer (IARC, 1990). Cr toxicity leading to severe health implications like; nasal irritation, lung carcinoma, hearing impairment, causes mutations and genotoxic abnormalities (Stern, 2010; Mishra and Bhargava, 2016). It severely affects soil fertility and plant growth by the destruction of microbial diversity. Ni, Zn and Cu play an important role as a catalyst in various metabolic reactions in humans and plants as well, however, its excess concentration beyond the required amount makes them toxic and leads to disruptions of enzymatic reactions and metabolic processes (Nagajyoti *et al.*, 2010). Thus, the continuous entrance of metals through anthropogenic or natural sources into the various fractions of environments, results into severe toxicological effects on humans and plants as well, beyond exceeding concentration of their permissible limits.

Remediation Approaches

The increasing concentration of heavy metals into the environment is a drastic challenging problem which ultimately affects all the life forms present on earth in a direct way or sometimes indirect way. There are various remediation technologies that have been used for the removal and reduction of toxic heavy metals from contaminated areas. Removal of heavy metals from the environment is very essential for safe and healthy environment. Some useful remediation technologies are summarized as below:

Conventional

The conventional treatment approaches that involve various physical and chemical practices like chemical precipitation, ion exchange, electrochemical treatment technologies. But, all these methods have significant disadvantage of incomplete removal, high energy requirements, costly maintenance, and production of secondary pollutants and generation of enormous amount of toxic sludge (Chandra *et al.*, 2011). Metal remediation can be achieved by physical excavation and transport of polluted soil to landfills. Apart from the risk of metal dispersal during transport of contaminated sites, makes these methods more time consuming and expensive. Scarcity of landfills is also a big problem for the disposal of metal contaminated wastes. Therefore, the application of conventional approaches is not very reliable and suitable for the remediation of metal contaminated sites.

Bioremediation

Bioremediation is an ecofriendly cleaner technology for the remediation of organic, inorganic and metal pollutants present into the environment in safe and healthy way (Saratale *et al.*, 2007; Bhosale *et al.*, 2006). This technology uses biological systems, plants, animals including microorganisms. Past few decades, the use conventional treatment technologies for the clean-up of various contaminants from environmental matrices creating an indirect pollution problem for the living beings and environment by the generation of secondary pollutants and sludge (Chandra *et al.*, 2011).

Thus, conventional technologies are not very reliable and safe from environmental perspective. Bioremediation is a multidisciplinary approach; it involves both in-situ as well as ex-situ method of treatment for any kind of contaminants. Microbes are best suited for bioremediation technology because of their vast adaptability in any environment. Microbes are easily adapted and grow in extreme environmental and nutritional conditions. The microorganism can be utilized in bioremediation practices in several ways such as:

- (1) *Biostimulation*: This process enhances the activity of indigenous microbes with the addition of adequate amounts of nutrients, water and oxygen into the soil. Application of different rate limiting nutrients and electron acceptors such as carbon, nitrogen and phosphorus are required for the modification of existing environment and facilitate the metabolic activities and growth of native bacterial population for the effective bioremediation. The main advantage of this application is that bioremediation process carries out by indigenous microbes that are well suited and spatially distributed in the contaminated environment (Simpanen *et al.*, 2016).
- (2) *Bioaugmentation*: It is the practice of addition of microbial culture to the soil and water subsurface to speed up the process of biodegradation. Microbes that are isolated from site of pollution are able for the degradation or transformation of pollutants, but sometimes this process is very and inefficient. So the introduction of exogenous varieties of microbes can improve the remediation process (Anjaneyulu *et al.*, 2005).
- (3) *Bioventing*: It is one of the promising new technologies, which boost-up the natural in-situ biodegradation of any aerobically degradable compounds in soil by providing oxygen to existing soil microorganisms. It mainly stimulates aerobic biodegradation with the help of delivering pure oxygen into the unsaturated zone through gas injection or extraction wells installed into the soil (Brown *et al.*, 2017).

Rhizoremediation

Rhizoremediation is a specific process of phytoremediation which shows the keen relationship between rhizospheric microorganism and plant root zone for the degradation and detoxification of heavy metals and other toxic pollutants (Thijs and Vangronsveld, 2015). Microbes can form a close relationship with the root region of plant including its root tissue system, root surface known as “**rhizoplane**” and in the soil particles attached to root region known as “**rhizosphere**” (Gaskins *et al.*, 1984). A variety of microorganisms can be found in the rhizosphere micro-habitat but, the highest proportion of microorganism which inhabit the rhizosphere are bacteria and fungi. Among bacterial population, *Pseudomonads* are well reported for their dominating space in the rhizosphere. These bacteria live in the root region of plants in metal contaminated soils by developing survival strategies like: resistance to metal either by sequester/bioaccumulate or biosorption process into the cell. Rhizospheric microbes are also able to transform toxic metal state to non-toxic or less toxic by enzymatic detoxification mechanism or by exo-polysaccharide production (Kamaludeen and Ramasamy, 2008). Root associated bacteria and fungi interact with plant improves plants growth as well fertility of soil.

Role of Rhizospheric Microorganisms in Plants Growth and Remediation of Metal Contaminated Sites

Plant Growth Promoting Rhizobacteria (PGPRs)

PGPRs play an important role in the rhizospheric microbial community. These microbes can directly increase the bioremediation process by altering the metal availability through the production of various phytohormones, changing pH, discharge of chelator etc. Mostly PGPRs endorse plant growth directly by enabling resource procurement as or by diminishing the inhibitory effects of several pathogens on plant growth in the form of bio-control agent (Glick, 2012). *Pseudomonas*, *Bacillus*, *Brevibacillus* are well known to promote growth and yield in different hyper accumulator plants and used in rhizoremediation of metal contaminated environments. PGPRs also act as biocontrol agents, which do not necessarily inhibit pathogens but increase plant growth through the improved cycling of nutrients and minerals such as nitrogen, phosphates and other nutrients (Ryan *et al.*, 2008). Most of the phosphorus and potassium available in the soil is in the insoluble form and cannot be utilized by plants. Phosphate solubilizing rhizobacterial strains have ability to solubilize insoluble phosphorus with the production of organic acids and enhance minerals availability to plants (Meena *et al.*, 2014; Gusain *et al.*, 2015). There are two common types of PGPRs associations are found in the rhizosphere zone are: (a) Extracellular plant growth promoting rhizobacteria (ePGPR) and (b) Intracellular plant growth promoting rhizobacteria (iPGPR) on the basis of their interaction with root cells of host plant (Bhattacharyya and Jha, 2012; Glick, 2012). Metal resistant PGPRs strains are capable to tolerate high concentration of toxic metals and possess efficient uptake and accumulation of heavy metals and therefore can be effectively used in metal contaminated environments.

When PGPR are introduced to a contaminated site, they increased the potential for plants that grow there to sequester heavy metals and recycle nutrients, maintain soil structure, detoxify chemicals and control diseases and pests. PGPR also decreases metal toxicity by developing mechanisms of biotransformation, biosorption, bioaccumulation, and biomineralization. In this multi-component system, the plants in turn provide the microorganisms with various essential root exudates such as free amino acids, proteins, carbohydrates, alcohols, vitamins and hormones, which are important sources of their nutrition. The rhizosphere has high concentrations of root exuded nutrients and attracts more bacteria than does bulk soil.

These bacteria of the rhizosphere, facilitate plant growth by increasing nutrient uptake availability, produce phytohormones like indole 3-acetic acid (IAA) and provides protection to the plants against pathogenic attacks by bio control and antagonistic activities (Ahemad, 2012). PGPRs can remediate the contaminated environment by affecting plant growth

through direct and indirect mechanism includes siderophore production, phosphate solubilization and production of 1-aminocyclopropane-1-carboxylate (ACC) deaminase and other plant growth, which provide resistance to plants against higher concentration of toxic metals and helps in the detoxification, bioaccumulation and transformation of toxic metals into less toxic or non-toxic states (Bhattacharyya and Jha, 2012; Glick, 2012).

Mycorrhiza

Rhizoremediation through the application of mycorrhizal fungi is a viable approach for the decontamination of polluted environments in a natural way. This not only helps in the biodegradation of soil contaminants but, also stimulates the soil fertility and microbial diversity by increasing nutrients uptake ability of plant (Chibuikwe, 2013). Heavy metals like Cd, Zn, Pb, Cr and As adversely affects soil properties by reducing microbial diversity and nitrogen fixation ability. "Mycorrhiza" is the symbiotic relationship between the fungal species and roots of vascular plants. Mycorrhizal fungi help in improving plant growth by increasing surface area of the plant's roots which enhances its nutrient and water uptake ability from soil. It increases the bioavailability of nutrients especially phosphorus and nitrogen, reduces environmental stress related with low level of water and increasing the resistance to pathogenic microorganisms by stimulating phyto-hormones (Merkl *et al.*, 2005; Kohler *et al.*, 2007).

Mycorrhizal fungi can protect plants from abiotic (e.g., increased heavy metal concentrations) and biotic (e.g., soil-borne pathogens) stress through enhanced nutrient supply. It actually acts as filters for plants that prevent the entrance of toxic metals by the use of their mycelium. However, plants in reverse provide nutrients substances like carbohydrates for the survival and growth of fungal cells. Mycorrhizae can only be found in plant roots hence they can also be called as modified form of rhizoremediation that explores the beneficial effects of mycorrhizal fungi.

There are mainly two common types of mycorrhizal associations are seen in plants: ecto-mycorrhizae (EM) and Arbuscular mycorrhizae (AM). Among which, Arbuscular mycorrhizae (AM), has been recently proved to remove toxic pollutants and enhanced rate of rhizoremediation by improving soil structure and plant tolerance to toxic metals and organic and inorganic pollutants (Chibuikwe, 2013). AM can alleviate root exudation process which also helps to improve rhizospheric microbial activity and remove pollutants by plants uptake and accumulation.

Metal-Microbe Interaction

Microorganism especially bacteria are believed to be the most diverse organism on earth which are ubiquitous and can survive in any extreme or inadequate conditions. They are able to evolved different tolerance mechanisms under stress condition for their survival. Moreover, in response to direct exposure to metal pollution, microorganisms have developed metal tolerance mechanisms under metal polluted environments. Microorganisms play an important role and in the remediation of metal contaminated soil and wastewaters. Microorganisms offer an ecofriendly and cost effective approach for the removal of toxic metal pollutant with considerable operation flexibility. Microorganisms are capable to degrade or reduce a wide range of pollutants including organic, inorganic and metals (Lloyd and Lovley, 2001). However, metals cannot be purely degraded or destroyed by microorganisms, but, they can influence metals mobility in the environment by altering or transforming their chemical and physical states (Eccles, 1999). Continuous discharge of industrial wastes, have resulted in the accumulation of high concentration of toxic metals into the environment. It has been well reported that microorganism especially bacteria capable to reduce metals from their highly toxic state into less toxic or non-toxic state by developing a variety of resistance mechanisms (Silver, 1992). Bacteria possess various types of heavy metal resistance mechanism including cellular accumulation, biosorption, intracellular and extracellular sequestration, plasmid resistance and enzymatic reduction or detoxification (Maier *et al.*, 2009). Microbial interaction with metals is highly advantageous in bioleaching, bioventing, bio-transformation of complete or partial mineralization of metal contaminated sites (Ehrlich, 1997).

Microbes have significantly affected the bioavailability and mobility of metals into the environment. Microorganisms secrete a variety of inorganic metabolic products of carbonate, sulfide, phosphate ions to form precipitated complex with toxic metals ions by the process of non-enzymatic detoxification. Microorganisms have evolved metal tolerance due to their direct or indirect exposure to toxic metals (Bopp *et al.*, 1983). The continuous interactions between metals and microbial cells increase the adaptability to survive in metal contaminated environment. In response to metal resistance into the environment, microbes have evolved indigenous mechanism of metal resistance and detoxification. However, various ways of interactions between metal and microbial cells are presented in Fig. 1. Microbial cells can immobilize toxic metals via cellular sequestration and accumulation. Toxic metal cations such as Cr^{+6} , Cu^{+2} , Pb^{+2} , As^{+3} and Hg^{+2} cope with negatively charged groups carboxyl, phosphoryl and hydroxyl of bacterial cell wall through adsorption and retained by mineral nucleation (Wase and Forster, 1997).

Metals Stress Tolerance Mechanism of Rhizospheric Microbial Community

Rhizospheric microorganisms deserve special attention for the remediation of metal contaminated environments, as they not only being useful for the remediation purpose but, they also have the advantage to promote the growth of plant in such metal contaminated environment by developing different kinds of metal resistant strategies. The most common mechanisms includes synthesis of metal-chelating siderophores, production of phytohormones, secretion of EPS, and biosurfactant production, helps in the removal of toxic metals and promoting plant growth and development. There are following some mechanism by which rhizospheric microbial community survive under metal stressed environments.

Fig. 1 Various ways of metal-microbe interaction.

By Exopolymer Binding

To survive under metal contaminated environment many bacterial strains secrete certain extracellular exo-polymeric substances (EPS) that are highly slimy in nature and help to reduce the bioavailability of heavy metals. These exo-polymeric substances are made up of polysaccharaides, nucleic acids, carbohydrates and fatty acids. These EPSs plays an essential role in binding of heavy metals and provide protection to microbial cell to abiotic and biotic stress conditions of desiccation, phagocytosis and parasitism (Gonzalez *et al.*, 2010; Kazy *et al.*, 2002). Since, metals are positively charged and bind with negatively charged functional groups are greatly influenced by changing pH of the stressed environment. Bioremediation of metals through EPS results in immobilization and hindrance the entry of metals into the microbial cell (Maier *et al.*, 2009). Nocelli *et al.* (2016) reported that Wild and mutant types strain of *S. meliloti* are able to produce to EPS I and EPS II under higher concentration of Hg (II) and As (III) and EPS producing mutants strains were found more sensitive to these metals. Rhizobacterial strains belong to genera *Mesorhizobium*, *Sinorhizobium*, *Bradyrhizobium*, and *Rhizobium* are widely reported for the production EPS and Biofilm formation in metal contaminated environment (Rinaudi and Giordano, 2010). EPSs provides protection to the bacterial cell in metal contaminated environment by the precipitation of metallic cations, or by binding to metal ions as reported in *Bradyrhizobium* and *Rhizobium*, respectively (Corzo *et al.*, 1994; Foster *et al.*, 2000).

By Siderophore Complexation

The production of siderophore by the rhizospheric microorganisms is an important feature which helps in the acquirement of heavy metals by metal chelating properties. Siderophores are normally low molecular organic chelating substances produced by bacteria and fungi, have the ability to form complexes with metal ions, and helps in sequestration of iron under low iron conditions (Neilands, 1995). Under metal (Cd, Zn, Al, Pb) stressed environment, siderophore production is induced by *Pseudomonas* and *Rhizobium* spp. to form steady complexes with these heavy metals and increase soluble metal concentration and alleviated the metal stress (Ganesan, 2008). Siderophore production enhanced plant growth by increasing protein content and chlorophyll content and decreases the heavy metal accumulation (Burd *et al.*, 2000). Rhizospheric bacteria increase the iron uptake ability of plant roots, from the complex ligand siderophore compound that are produced by them to increase the growth and development of plant and remediate metal contaminated environment (Rashmi *et al.*, 2013). Heavy metals, damages cellular membrane and disrupt the functioning of ferric reductase, and hence reduces iron uptake and result in iron deficiency in plants as chlorosis. Bacterial siderophores preclude iron deficiency and helps in the production of growth hormones under metal pollution conditions. It enhances auxin synthesis in the presence of Al, Cd, Cu, and Ni by chelating them and decreases metal contamination and promote plant growth (Seneviratne and Vithanage, 2015).

By Biosurfactant Complexation

The toxicity of heavy metals is depended largely on their solubility and bioavailability. Most of the metals can form complexes with soil particles. This lack of bioavailability often lowers removal efficiency (Johnson *et al.*, 2005). Rhizospheric bacteria use different strategies to promote the bioavailability of toxic metal compounds with the excretion of biosurfactant. Biosurfactants are amphiphilic molecules that form spherical or lamellar micelle concentration exceeds a critical micelle concentration that is specific for each compound.

Hydrophobic contaminants become solubilized in the hydrophobic cores of the micelles, which increases the transfer of the compound from a solid to water phase where it becomes more accessible to bacteria (Segura *et al.*, 2009).

Rhamnolipids has been reported as one of major biosurfactant produced by bacteria under metal stressed environment which increases the biodegradation rate of pollutant (Mulligan, 2005; Cui *et al.*, 2008). The selection and application of rhizobacteria, which stimulate the bioavailability of metal is therefore of great interest in the context of metal remediation. Currently, bio-surfactant complexation have been investigated for their ability to bind with heavy metals like Cd, Pb, Zn, Cr and As to form complex compounds with increasing solubility that is non-toxic to the cell.

Economic Importance

Rhizoremediation can be successfully used for the restoration of contaminating sites by the right selection of plant cultivar with potential rhizobacterial strain on field trials. The proper inoculation of efficient rhizobacterial strain enhances hyper accumulation ability of plant for commercial phytomining. Rhizoremediation do not needs expensive treatment maintenance and chemical reagents, which make it an ecofriendly and economically suitable technology for the safer use in the progression of environment and farmers to reduce the use of chemical and expensive remedial practice for the removal of toxic pollutants.

Conclusion

Rhizoremediation is a becoming a popular sustainable practice in forestry and agricultural management for the remediation of various pollutants and contaminants. This technology is largely useful in metal contaminated soil areas with nutrients deficient conditions. It involves the use of cheap renewable resources like PGPRs and Mycorrhizal fungi making it more profitable than other remedial technologies as it can be used as fertilizer and prevents the use of pesticides naturally. Thus it is more convenient, environmental friendly and economically profitable approaches instead of other conventional practices.

The Potential Role of Re-Distributed Manufacturing in Improving Industrial Sustainability

Rachel Freeman, University College London, London, United Kingdom

Chris McMahon, University of Bristol, Bristol, United Kingdom

Introduction

Mass manufacturing was a central part of the industrial revolution, and up to the later part of the 20th century much of manufacturing production was carried out within urban areas – in fact manufacturing businesses financed much of the building of cities in developed regions (Schmenner, 2009). Mass manufacturing has largely disappeared from city centers in industrialized nations, having been moved to lower-cost global regions or dedicated manufacturing plants typically on city outskirts – as, for example, German automotive plants are. Manufacturing production in developed global regions is now largely restricted to niche consumer goods; high-value products including pharmaceuticals, vehicles and specialist high-tech artefacts; perishable goods such as food and medical supplies; and low-value bulky goods such as steelwork for construction, building parts and materials.

Manufacturing organizations carry out many types of activities, including: (i) technology and materials research, (ii) product design and development, (iii) supply chain management, (iv) production (fabrication), (v) sales and distribution logistics, (vi) in-life service, (vii) product remanufacturing (the reprocessing of parts in used products or the replacement of components in a used product, which bring products to a like-new condition (Atasu *et al.*, 2008)), (viii) product refurbishment or reconditioning (product is returned to satisfactory working condition by replacing or repairing major components that have malfunctioned or are close to failure, product is as good as new (Leino *et al.*, 2016)), (ix) product repair (specified product faults are corrected, product can be less than new (Leino *et al.*, 2016)), and (x) product take-back (collection of used products and their recovery or proper disposal (Klausner and Hendrickson, 2000)).

Re-distributed manufacturing (RDM) has been defined as “technology, systems and strategies that change the economics and organization of manufacturing, particularly with regard to location and scale” (Pearson *et al.*, 2013). Out of all the activities associated with manufacturing listed in the previous paragraph, RDM is focused mostly on production, repair, refurbishment, and remanufacturing. The main idea behind RDM is that physical manufacturing activities can be transferred from large-scale, centralized facilities to small-scale facilities located closer to customers. A second definition of RDM, which takes into account its wider implications, is that it is the localization of the production of manufactured artefacts which has the potential to benefit economy, society and environment, and to improve supply chain resilience (Freeman *et al.*, 2017).

The RDM agenda is based on several enabling and driving trends:

- The growing availability of new types of technologies and materials that can be used in fabrication, repair and remanufacturing (e.g., 3D printing). New technologies can allow small-scale production of products that would otherwise be made in large production plants (requiring large capital investment), and they can enable production and repair costs to be reduced through gains in production efficiency (e.g., with automation) – meaning manufacturing in high-cost regions becomes cost-competitive.
- The growth of the digital economy, which enables improvements and cost reductions in the non-production part of manufacturing activities, especially in customer interactions, business to business collaboration, and distribution and take-back logistics. Digital technologies can support collaboration with other companies even if located remotely; and allow access to individual and business customers all around the world.
- The growing number of new types of sustainable business models, enabled by the digital economy, which can work at varying scales and especially for small to medium enterprises (SMEs). New business models, especially “local to local” or “local to global”, can allow flexibility in how products are made, sold and serviced; allow companies to adopt a more circular use of materials, and improve their sustainability (Bocken *et al.*, 2016). These business models are especially beneficial for emerging industries and supporting increased innovation in manufacturing processes (Srai *et al.*, 2016).
- The RDM agenda is also being driven by the increasing demand for customization or personalization of products and services, and the increasing enhanced participation of designers, producers, and end-users across the manufacturing value chain (Srai *et al.*, 2016).

Classification

A dominant trend in the past few decades has been the off-shoring (transfer) of manufacturing production to low-cost regions, by manufacturers based in high cost regions. For many reasons, including higher than expected costs and supply chain risks, more recently the strategy of re-shoring is being adopted by many manufacturers (moving some of all of their production back to the country in which the company is based (Moradlou and Backhouse, 2016)). Drivers for re-shoring include: the narrowing of differentials in labor costs between global regions; higher transport costs; greater need to be close to target markets; product quality concerns; advantages of co-location of design, R&D and production; and changing energy costs (Foresight, 2013).

RDM aligns well with the drivers for re-shoring, especially in being able to locate production closer to customers, co-locate R&D and production, and making use of the increasingly reduced differences in labor costs between global regions. Where best-shoring or right-shoring is the chosen strategy (in which the optimum balance of production on-shore versus off-shore is derived from careful analysis of determining factors (Fox, 2015)), use of RDM could allow the proportion that is re-shored to be increased. RDM could also support on-shoring (the setting up of completely new manufacturing organizations and facilities in higher-cost regions (Fox, 2015)). Although on-shoring is not exactly RDM, since there is no *re*-distribution, the approach could be applicable and provide similar types of benefits.

RDM is similar but different to the following classifications of the organization of manufacturing:

- Decentralized manufacturing, in which large centralized manufacturing plants are replaced with numerous smaller manufacturing units, providing benefits in reduced delivery times and transportation costs, and increased agility (Mourtzis and Doukas, 2012). Manufacturing can be spread over distributed production structures such as replicable, scalable, reconfigurable, or changeable (smart) model factories (Matt *et al.*, 2015). Decentralized manufacturing differs from RDM in that no assumptions are made about re-shoring or on-shoring, or novel technologies that enable small scale production, or industrial sustainability improvements.
- Distributed manufacturing refers to the geographical distribution of the production of one organization, or the distribution of manufacturing within a dispersed production network of autonomous agents (Rauch *et al.*, 2016). Distributed manufacturing differs from RDM in that there are no assumptions about production being close to customers or happening in smaller production units, or in using new production technologies.
- Agile manufacturing is an approach to manufacturing with key characteristics that include: highly customized products; an ability to mobilize core competencies; responsiveness to social and environmental issues; synthesis of diverse technologies; responsiveness to change and uncertainty (Yusuf *et al.*, 1999). Agile manufacturing differs from RDM in that there are no assumptions about offshoring or reshoring, location in relation to customers, small scale production, or use of new technologies; it is similar to RDM in its focus on responsiveness and customized products.

Technologies Used in RDM

A wide range of technologies can be used in RDM. Following is a list of example technologies; this is by no means a comprehensive list, and in fact new technologies are in development all the time that could be useful in RDM, but it represents the most important ones to RDM at the time of writing.

- (1) Additive layer manufacturing technologies, such as 3D printing, are techniques with which complex geometries can be produced directly from digital designs “through the sequential solidification of layers of material” (Li *et al.*, 2016). Additive layer technologies can be used to create prototypes and to do small scale production; their flexibility allows the optimization of design for lean production; their use can improve resource efficiency and allow more flexibility in production (Huang *et al.*, 2013). Their suitability for small-scale and customizable production makes them a key technology for RDM.
- (2) Laser additive technologies are particularly suitable for the repair, refurbishment and remanufacturing of used products, an important potential benefit of RDM. Example applications include gas turbine blade repair, mould and die repair in the tooling industry, reconditioning of crankshafts, and refurbishment and repair of structural components in the aerospace industry (Leino *et al.*, 2016). Additive manufacturing can be used to carry out maintenance, repair and overhaul of specialist equipment parts such as adding laser cladding to high-volume aerospace, automotive, marine, or rail components, where excessive wear has occurred (Wits *et al.*, 2016).
- (3) Digitally controlled cutting tools such as laser cutters can be used to improve a wide variety of types of production, including traditional small-scale production and prototyping. For example, a producer of leather goods combines traditional leather making skills with computer-aided cutting machines, new splitting and buffing machines and other facilities to improve efficiency and keep producing their products on-site (Thomas Ware leather goods: see “Relevant Websites section”).
- (4) Automation and robotics are envisaged as part of the concept of Industry 4.0 – “highly developed automation and digitization processes...the use of electronics and information technologies (IT) in manufacturing and services” (Lu, 2017). This approach may better suit large scale production due to its high set up costs; however, automation and robotics can also be used to reduce costs and improve efficiency in smaller scale facilities. For example, a UK company manufacturing plastic hangers for retail display of footwear was able to re-shore five manufacturing jobs through a program of production efficiency improvements including automation of assembly processes (*Bristol jobs boost as plastics manufacturer Phineas Group brings production home*: see “Relevant Websites section”).
- (5) Big data, the gathering and analysis of a wide range of manufacturing, product and customer data, is being used by some consumer goods companies to support consumer-inclusive co-creation practices. The analytics provided by data science helps companies to define customer motivation and identify opportunities for co-innovation and co-production between producer and customer – leading to more adoption of RDM business models (Zaki *et al.*, 2017).
- (6) Digital fabrication is the ability to send product designs digitally across the world (Gershenfeld, 2012) and make products locally, rather than making products centrally and shipping them to different locations. This fits with the idea of RDM in bringing production closer to customers and small-scale production and prototyping with innovative production technologies.

- (7) New composite materials that incorporate recycled waste can improve product sustainability. For example, polymers from carpet waste are being combined with other raw materials and used to make products in a molding process (Wang, 2010); wood wool composite boards are being used for building insulation, and natural fibers are being added to bio-composites (Mohanty *et al.*, 2002). New technologies allow composite materials to be made in small batches with locally available materials, further improving sustainability. For example, a small company in the UK is making furniture from composite material that incorporates locally available waste wool (Solid Wool furniture: see “Relevant Websites section”).
- (8) Makerspaces are community workshops that allow visitors to develop new product prototypes and experiment with materials and product designs, including digital fabrication. Makerspaces could play a vital role in evolving sustainable design and manufacturing practices, and in overcoming some of the challenges of increasing RDM, including: (i) Scalability (maturing from prototyping to batch production, supply chain management issues, developing knowledge of production management, identifying and developing means to access local markets); (ii) Context (developing routes to local integration, methods to access and manage local material supplies); (iii) Collaborations (meeting the need for collaborations with other producers) (Prendeville *et al.*, 2016).

Applications of RDM

Responsive RDM has been envisaged as forming a part of the future production landscape, with more urban manufacturing and responsive “reconfigurable units integrated with the fluid requirements of their supply chain partners” (Foresight, 2013). Little data exists on how much RDM has affected manufacturing sectors to date, but it is likely that only a very small percentage of total manufacturing production has been redistributed. The use of additive layer technologies, one of the more common technologies used in RDM, is estimated to account for less than half a percent of global manufacturing value (Li *et al.*, 2016). Some re-shoring of manufacturing in developed regions is happening in transportation goods, computers and electronics, fabricated metal products, machinery, plastics and rubber, appliances and electrical equipment, furniture, ceramics, and textiles. Low volume products, for example automotive and aerospace parts, appliances and construction equipment in which labor accounts for a minor proportion of total costs, are considered to be the most suitable for re-shoring (Foresight, 2013).

RDM is not suitable for all types of manufacturing. For many cheap consumer goods, like toothbrushes, the benefits of centralized production in terms of economies of scale currently outweigh the potential benefits of RDM. However, general moves towards production that is smaller scale, distributed and more localised have been seen in how manufacturing is organised; in future it is predicted that large scale production will no longer be globalized by default, and regionalisation or even localization will occur in many sectors (Livesey and Thompson, 2013). There are several practical factors influencing the trend towards adopting smaller scale, dispersed manufacturing options: improved industrial sustainability, the democratizing effect on participation in industrial systems at a socio-economic level, the incentive to make supply networks more adaptive and responsive; the ability to increase product variety while reducing inventory size (Srai *et al.*, 2016).

There are several types of potential applications of RDM.

- RDM can occur in existing sectors where some combination of automation, robotics and different types of efficiency improvements such as Lean Manufacturing is able to reduce the cost of production enough to make re-shoring or localizing production economically viable. There may not be any particular innovation in product design; the innovation comes in how products are made and in finding potential for remanufacturing or repair.
- RDM can be used by companies providing on-demand supply of bespoke, high-value and technically innovative products; these are often customized to individual customers. Examples include medical devices and implants, pharmaceuticals (Roscoe and Blome, 2016), and parts for high-tech and specialist industries such as aerospace and the defense industry (Busachi *et al.*, 2017). This could be done by SMEs supplying large enterprises or by large enterprises replacing some of the products sourced from supply chains with in-house on-demand fabrication.
- RDM can be the basis for the growth of companies specializing in repair, remanufacturing, refurbishment, and reconditioning of products – which could be the original equipment manufacturer or smaller companies that only do this type of work. RDM can change the economics of such processes since innovative technologies allow them to be done on a wider variety of products and they can be done closer to customers – reducing wait times, simplifying take-back logistics, and reducing shipping costs (Wits *et al.*, 2016).
- RDM fits with the niche product market, where the location of production is part of the selling point of the product, or products are highly specialized but not necessarily high-tech. The niche aspect allows higher sales prices and therefore justifies the higher production costs in high-cost regions. This is not strictly re-distributed manufacturing, since it includes production that was never centralized or offshored, but it prevents even more centralization and job losses and the expenses of re-distributing manufacturing at a later date. Niche manufacturing contributes to the local economy through local jobs, local taxes, retaining local expertise in product making and product design, and other local economic activities such as tourism. Examples include regional food specialties (e.g., whisky from Scotland), products made in niche industries with a local history (e.g., Cameron Balloons (Cameron Balloons: see “Relevant Websites section”)), and traditional local making skills combined with new digital tools.

In terms of which types of enterprises could apply RDM, this will vary by size of company, the type of goods or services, the business model, and the location of customers. Companies may produce goods locally for local sale (e.g., food products, spare

Table 1 Types of manufacturing enterprises and their potential for using redistributed manufacturing (RDM) in improving organizational sustainability and industrial sustainability. Scoring is as follows: 1 = low, 2 = medium, 3 = high. B2B = “business to business”; SME = small to medium enterprise; LE = large enterprise

Type of enterprise	Examples from the UK	Where and to whom enterprises sell	Drivers for RDM	Future RDM Potential and Drivers			
				Susceptible to technology disruption	new products and growth	new jobs, especially semi-skilled	sustainability and resilience
Sole trader makers	Violin makers, tailors, jewelry makers	Direct to customers in the area and via internet	Improve access to customers, reduce production costs	1	2	1	2
Product based SMEs, niche producers	Cameron Balloons, Solid Wool Furniture	Customers & retailers, in the area & export	Localism, local production	1	2	1	2
SME high tech makers/designers	Local suppliers to large high-tech companies	Mostly B2B, in the area and export	Competition, staying in manufacturing cluster	3	3	2	3
Low tech makers	Print shops, steel fabrication, joinery	Mostly B2B, mostly local to local	New types of jobs	1	1	2	3
Product based LEs	Few existing companies but future potential	Mostly to retailers, in the area and export	Competition with global manufacturers & mass customization	2	2	1	2
SME food production	Fresh food, dried foods, specialty drinks, etc.	Mostly in the area, some global distribution	Local branding, exports	2	1	2	3
High tech LEs	Aerospace, defense, pharmaceuticals	Almost all export, global	Global competition	3	2	2	1

parts for local industries), or produce goods locally for national or international sales (e.g., bespoke jewelry sold over the internet, customized medical devices shipped overseas). SMEs could especially benefit from the RDM model, increasing the ability to customize solutions for their customers while minimizing environmental impacts by locating technology, people and materials close to markets (Ball and Jolly, 2015). RDM could help established companies deal with the threat of technology disruption – technology innovations that are “disruptive to both producers and consumers and...a result of supply push processes originated by entrepreneurs rather than incumbent firms” (Albors-Garrigós and Hervás-Oliver, 2013).

Table 1 outlines different types of enterprises and the potential for them to benefit from RDM in different ways.

Industrial Sustainability

Rauch *et al.* (2015) identify four key elements in industrial sustainability: economy (cost of energy and materials), ecology (rate of use of resources), social (workplace welfare, skill levels), and political-institutional (public funding for sustainable manufacturing); the authors find that while the concept of distributed manufacturing systems could play a major role in improving industrial sustainability, it cannot be applied within every industrial sector and for every product. Potential sustainability benefits of RDM include: reduced shipping distance between production location and customers (saving energy and emissions from transport), improved material efficiency of production (saving materials), improved opportunities for remanufacturing and repair that extend usable lifetime of products and parts, new uses for locally available materials that would otherwise have been wasted or which would no longer be cost-effective to use (including natural materials such as leather), and the use of new composite sustainable materials in innovative product design.

Kohtala (2015) conceptualized the future distributed production landscape as consisting of: bespoke fabrication, personal fabrication, mass customization and mass fabrication – each with its own potential environmental benefits and concerns; however, the author states that there is no certainty that distributed production will lead to a new and clearly cleaner manufacturing paradigm. Additive layer manufacturing in particular can enable improved sustainability within the processes of “product and

process redesign; material input processing; make-to-order component and product processing; and closing the loop” (Ford and Despeisse, 2015).

In theory, products made through RDM might be expected to be less environmentally impactful than products that arrive through a long supply chain, especially if made “local for local”, yet there are several open issues that remain to be addressed:

- There needs to be sufficient and appropriate environmental regulation for RDM, and this is more difficult to implement when production is small-scale and distributed, especially for enforcement of regulations; furthermore, ensuring compliance with regulation is more difficult for smaller companies where having in-house expertise may not be affordable.
- There is a lack of evidence on whether RDM processes are more or less energy and material efficient than mass manufacturing (Huang *et al.*, 2013); material efficiency depends upon the product design, its material construction, and its lifetime of use.
- Some technologies used in RDM, such as 3D printing, produce products that are not recyclable or repairable. Polymer feedstocks used in 3D printing are made from fossil fuels, and the production of powder metals involve vacuum and inert gas processes which may have significant environmental impacts (see “Relevant Websites section”).
- Customized products may not be as reusable as mass produced products since they are not made for universal applications and may not be designed for disassembly at end of life.
- Re-shoring of manufacturing would also re-shore some of the negative environmental impacts in the country to which manufacturing has been transferred: energy use and associated greenhouse gas emissions (depending on carbon content of energy used), consumption of raw materials (including increased imported materials), consumption of water, creation of waste, and increased freight on transport networks. This may or may not lead to a net increase in environmental impacts, depending on aspects such as level of mechanization and automation and the types of energy and materials used, but environmental accounting should keep track of this.

Economic Benefits of RDM

RDM has been described as epitomizing an on-demand economy, with a growing number of local manufactories helping to reconfigure and redefine product markets and supply chains, invoking new decentralized business models (Pearson *et al.*, 2013). Those manufacturing companies that apply resiliency and business sustainability models – for example, Six Sigma, quality management, lean, fit manufacture, knowledge management, etc. – generally achieve better business sustainability (Thomas *et al.*, 2016) (where the term “business sustainability” indicates that businesses are able to stay afloat indefinitely). However, even these efficiency improvements may not be enough to achieve business sustainability in a fast-changing globalized business environment, especially where there is constant threat of disruptive technological change. Organizations must also be flexible and agile, such as through establishing collaborative supply chain relationships based on transparency of key information (Christopher and Peck, 2008), and evaluating the use of advanced manufacturing technologies in a way that goes beyond standard economic criteria (Mohanty and Deshmukh, 1999).

RDM has the potential to improve flexibility and agility for individual companies, and to provide secondary benefits to local economies, including: new workforce skills and manufacturing specialties that improve the competitiveness of the local economies of cities and regions, new semi-skilled jobs especially in communities that have been left behind by deindustrialization, and the application of traditional making skills in a novel way to ensure their longevity and the survival of local cultural heritage.

The Future for RDM

As indicated in Table 1, there is likely to be some potential for RDM in all sectors. A summary of three studies into RDM follows, as examples of how RDM can align with the particular needs of product types.

In the consumer goods sector there is potential for RDM to support a circular economy when combined with “digital intelligence” (the ability to understand and interact with digital information, and to arrange, manipulate, and display it (Adams, 2016)). More understanding of where value is captured and delivered will be essential for identifying the significant opportunities that exist (Moreno and Chamley, 2016). A case study (the Shoe Lab) developed a model of implementation of RDM for sports shoes, which includes: (i) customer 3D scanning of their feet at home; (ii) customer use of virtual reality technology to customize the shoe design on-line; (iii) the choice to pay outright or subscribe; (iv) “smart” shoes embedded with sensors that can track location, performance data and shoe condition; (v) shoes 3D printed to the customized design, with manufacture (and re-manufacture/ upgrade of components) taking place close to customers; (vi) Shoe brand can forge data-driven relationships with users via digital intelligence, enabled through new business models (Keely *et al.*, 2016).

In the healthcare sector, RDM has the potential to change how products are delivered, transforming the manufacture of medical devices, pharmaceuticals, biopharmaceuticals and regenerative medicinal products (Phillips *et al.*, 2018). In fact, the top three fastest growing segments for additive layer manufacturing are medical and dental diagnostics and treatment, and medical prosthetic devices including dental implants (Li, Myant and Wu, 2016). Key challenges to realizing the potential in healthcare products include: regulatory standards, the need for new training patterns, social and human factors, and new supporting organizational structures and commercial arrangements. In the long term, strong investment will be needed to enable RDM platform systems to deliver medical products rapidly,

at an affordable cost, and in a more sustainable manner than existing modes of production (Phillips *et al.*, 2018). Roscoe and Blome (2016) identified several niche applications in which RDM could be applied within pharmaceutical supply chains: “additive manufacturing could be used to create compound products such as infusion bags...in radio pharmacy radioactive drugs could be created at the hospital for immediate patient use...late stage dispensing using additive manufacturing technology could cut down on the waste currently generated from de-blistering” (Roscoe and Blome, 2016).

Srai *et al.* (2016) examined cross-sectoral issues related to RDM in emerging industries, identifying the nature of industrial innovations and the different types of advantages they provide, across six sectors: defense aerospace, maritime, built environment, industrial biotechnology, photovoltaics, and last mile logistics. The authors found that from a RDM perspective, (i) smaller scale and dispersed production options can improve industrial sustainability and democratize participation within industrial systems at a socio-economic level; (ii) RDM systems can drive more adaptive and responsive supply networks, supporting increased product variety while inventories are reduced; (iii) new e-Commerce models featuring digitalized supply chains can support “rapid replenishment and decoupled distribution channels, with drop-points located closer to end-users” (Srai *et al.*, 2016).

There are some practical considerations for the adoption of RDM in different regions and industries.

RDM activities will require some of the same supportive conditions that enabled mass manufacturing to thrive in the past – including a diverse manufacturing sector, high-tech manufacturing clusters, investment in new skills and technology innovation, local ownership of companies and industrial leadership, and investment in building and maintaining civil infrastructure that can host manufacturing. However, in many countries the importance of manufacturing to the economy is significantly lower than in the past, and it is uncertain how well RDM aligns with the goals of local, regional and national governments.

While RDM has been proposed as a way to bring back some of the semi-skilled manufacturing jobs that have been lost, so far most of the new jobs associated with RDM appear to be for highly skilled personnel. The contribution of RDM to reducing inequality has up to now been small, and even less than traditional manufacturing. In fact, there might be job losses for SMEs if large companies start to fabricate their own parts instead of buying in parts from suppliers. To create more semi-skilled jobs might require new business models and new types of public sector support. RDM business development, especially for SMEs, needs to be supported by local enterprise promotion of manufacturing clusters, academic and government support for technology innovation, ensuring companies can get space such as through planning zones that allow manufacturing, and skills training for the use of new technologies. Ensuring that products can be reliably shipped to customers, both local and global, is also key for business success, and with RDM rural transport links may become more critical.

Many of the services that manufacturing uses are supplied through infrastructure, and innovation in infrastructure can even stimulate innovation in manufacturing (Luger *et al.*, 2013). However, in developed regions many urban and suburban areas are now dominated by housing, retail outlets, distribution centers, and the services sector, and some developing regions are following this pattern. Competition for physical space will only become more intense in future due to the trend for urbanization, increasing prosperity in developing regions, and increasing population. Although RDM is small scale, it still requires some physical space, and cash strapped start-ups require spaces with cheap rents where manufacturing is allowed; rural and city governments should ensure that some affordable space remains for RDM and that its growth is not prevented through urban gentrification.

Strong growth in RDM would start to reverse the previous decade’s dominant trend for offshoring and centralizing production, opening up a wide range of potential benefits for startups, small to large manufacturing companies, companies dealing with technology disruption, traditional and sole trader makers, and local economies in general.

Funding

The research behind this book article was carried out at the University of Bristol, UK, as part of the network project Redistributed Manufacturing for the Resilient, Sustainable City (RDMIRSC), funded by the UK’s Engineering and Physical Sciences Research Council, grant EP/M01777X/1. The authors would like to sincerely thank all the participants in the RDMIRSC network.

Recycled Concrete

Mayuri Wijayasundara, Deakin University, Melbourne, VIC, Australia

Introduction

Concrete is the second most consumed material on Earth, after water. It is estimated that roughly 25 billion tons of concrete are manufactured globally each year (World Business Council for Sustainable Development, 2015). As the highest used construction material and the most widely used manmade material on Earth, concrete makes up a considerable portion of the world's waste. Concrete consists of cement, coarse and fine aggregate, and water primarily, together with other additives and supplementary materials. When a building constructed with concrete reaches the end of its life, it is demolished resulting in construction and demolition (C&D) waste. Concrete waste is part of the C&D waste stream, with other materials such as brick, wood, plastics, and other mixed waste. C&D stream is considered the single largest waste stream in the world, accounting for 30%–40% of the world's waste volume. Typically, demolition activity accounts for less than 10% of total C&D activity, yet demolition waste accounts for about 50% of the total C&D waste stream (Tam, 2008).

Construction and Demolition Waste

The extent of C&D waste stream as a part of the total waste generated differs within a large range among countries. Even among developed countries such as Japan (16%), the United States (29%), Australia (42%), and the UK (>50%) there are significant variations (Hiete *et al.*, 2011). Also per capita waste generation figures of different countries vary; as an example Norway with 0.2 tons per capita, Australia with 0.88 tons per capita, and the UK with 2 tons per capita, approximately (Tam *et al.*, 2008). Additionally, the extent of concrete waste in the C&D waste stream could also differ and these variations are due to different economic activities, differences in building tradition and materials, the maturity and current phase of the construction industry, and differences in data collection with inclusion and exclusion of specific streams such as earth excavations (Hiete *et al.*, 2011). An example would be that houses constructed mainly with wood in countries having four distinctive seasons would consume less concrete, whereas countries building more permanent structures traditionally (e.g., Asian countries) would consume more concrete. Therefore, when the C&D waste is recycled, the amount of recycled concrete in the stream will depend heavily on the construction industry practice.

Considering the C&D waste stream, concrete waste results from:

- (1) Construction waste: The residual concrete remaining in ready-mix concrete bowsers once the pouring is done, overordered concrete (wet concrete) or hardened concrete removed from structures at construction stage (dry hardened concrete).
- (2) Demolition waste: Concrete waste mixed with other rubble (such as bricks, asphalt, roof tiles, wood etc.) resulting from demolition of a structure.

For the purpose of this article, we consider the recycled concrete resulting from concrete waste from demolition waste as the main source, as it represents the majority of concrete waste. Recovery of wet concrete resulting from construction processes is not discussed in this article.

Concrete in Construction and Demolition Waste

Concrete waste in the C&D stream is either separated before and/or after recycling. The large concrete chunks could be separated from demolition waste prior to recycling and after recycling other embedded waste such as reinforced steel needs to be removed. The amount of concrete waste in the C&D waste stream is considered close to 50% in some studies (Tam *et al.*, 2009), while a few other studies report that it could be as high as 70%–85% (Nicolas *et al.*, 2008).

Recycled Concrete Production

Concrete waste is a two-phase material at a broad level: Coarse aggregate, which is used to provide volumetric stability to the original concrete and dried mortar, which acts as a binder of aggregates. The mortar phase typically consist of fine aggregates (sand) and hardened, hydrated cement slurry.

Once a construction containing concrete is demolished, some of the concrete waste may be mixed with other demolition waste, while some would remain intact and hence some would qualify for recycling and the rest would reach landfills. Recycled concrete can either be produced at the demolition site using a mobile recycling facility or can be transported to a fixed recycling facility, where it would be recycled. The resulting product from the recycling operation, which is typically a crushing operation, is referred to as crushed concrete or recycled segregation concrete.

Fig. 1 Construction and demolition waste sorting and steel reinforcement removal. Reproduced from MilBank, 2018. Waste Recycling, MilBank.

On-Site Concrete Waste

Some of the concrete waste resulting from demolition is often mixed with other materials such as, plastic, brick, steel etc., and some will remain unmixed as large concrete pieces, gravel, or fines.

If the demolished construction has contained reinforced concrete in its structure, the concrete waste would have steel reinforcement, binding the waste concrete together. To recycle concrete, some of this steel reinforcement is removed at the demolition site, to make the large concrete pieces transportable to a recycling facility. This process is illustrated in [Fig. 1](#).

The Recycling Process

In general, separation of concrete waste and crushing of concrete waste is referred to as concrete recycling, however, there could be variations to this process as discussed in this section.

Goals of the recycling process

The goals of the recycling process will largely depend on its destined use. Mainly, there are two different types of goals that the recycling process aims to achieve, based on the final properties of the recycled concrete. This would lead to use of two different categories of technologies as discussed by [Doshio \(2008\)](#). These are:

- (1) Achieve complete refinement, so that the coarse aggregate portion of the concrete will have equivalent properties to natural aggregate (NA) used to make the primary concrete.
Technologies used to achieve this goal fall under the broad category of “aggregate refinement method.” Complete refinement is achieved via completely removing the residual mortar attached to the concrete and separating out the fine portion of cement mortar in the recycled concrete. To achieve this, it is not usually sufficient to use crushing processes where the concrete waste is broken down to small particles. Chemical processes, such as heat treatment or other means such as scrubbing would be required, making the recycling operation energy intensive and costly in comparison. However, the main advantage is that the two main volumetric components, namely the aggregate and the mortar component would be fully phase separated at the end of a recycling process following aggregate refinement.
- (2) Achieve a coarse aggregate containing residual mortar in its surface, referred to as recycled concrete aggregate (RCA) and some fine aggregate with fine mortar.
Technologies employing the above are often referred to in research as aggregate replacement methods. This is achieved via crushing of the recycled concrete using an impact crushing process to reduce the particle size and then using another mechanical process (such as sieving or airlifting) to separate the coarse aggregate portion and the fine portion of the resultant material. The objective of the recycling process is to reduce the influence of mortar on the coarse RCA; however, the process does not intend to achieve complete refinement. Therefore, these technologies employed achieve a resultant material stream with partial refinement of the coarse aggregate with residual mortar on its surface and a fine recycled concrete aggregate (FRCA) portion. The subsequent processes using the coarse aggregate portion would need to take into account that the coarse recycled concrete would contain residual mortar and deal with it accordingly.

Recycling process

At a recycling facility, typically concrete waste undergoes manual and mechanical sorting (manual separation of large items and magnetic separation of steel reinforcement), impact crushing, and size separation through sieving. If there are oversized particles or

Fig. 2 Process steps of concrete waste processing to produce Recycled concrete aggregate.

contamination discovered during the sieving process, they are dealt with separately. The oversized particles would be diverted back to the impact crushing process, while contamination is separated through a technology such as airlifting. This is illustrated in Fig. 2.

Recycling technologies – To achieve partial refinement

The above process is sufficient to achieve partial refinement of the output product. The output, referred to as recycled concrete, therefore would consist of:

- (1) Coarse RCA – Typically above 5 mm in size, and with some residual mortar on the surface, typically 55%–73% of recycled concrete.
- (2) Fine RCA – Typically less than 5 mm in size, mixed with coarse RCA, typically 27%–45% of recycled concrete.

Recycled concrete containing these two materials is usually used as a road-base material or a filler material. The differing sizes of the two constituent materials do not pose a limitation in this application. However, as recycled concrete replaces a low-value use, this is generally regarded as a downcycled option.

Recycling technologies – To achieve full refinement

In addition to employing a typical crushing process, to achieve a level of refinement similar to that of NA, several technologies can be used. The main methods that are used at industrial scale include (1) heated scrubbing, (2) mechanical scrubbing (using eccentric rotor or a screw mill), and (3) wet scrubbing (Doshio, 2008). These methods are specifically used in Japan as the Japanese standards recognize high quality RCA as being similar in quality to NA used in concrete. The above methods use heat or mechanical scrubbing (dry – against each other or wet – using water) as a technique to embrittle the residual mortar attached to the aggregate. These processes that are used to achieve full refinement are presented in Figs. 3–6.

Some other methods trialed in laboratory and pilot scale to achieve refinement of the recycled aggregates include (1) nitric acid dissolution method, (2) presoaking method, (3) microwave heating method, (4) ultrasonic treatment method, and (5) surface modification methods (Behera *et al.*, 2014). The purpose of all these methods is to achieve low fracture energy in disintegrating mortar in concrete, ease the liberation of aggregate by improved surface conditions or weakening the mortar phase, and to remove the adhered mortar without losing the integrity of the original aggregate.

Properties of Recycled Concrete

This section will discuss the properties of recycled concrete that has achieved partial refinement, as that is the most generally available form of recycled concrete. Countries such as Japan have standards recognizing fully refined coarse RCA as equivalent to

Fig. 3 Operation of a heating grinder. Reproduced from Tomosawa, F., Noguchi, T., Tamura, M., 2005. The way concrete recycling should be. *Journal of Advanced Concrete Technology* 3, 3–16.

Fig. 4 Operation of an eccentric rotor-type mechanical grinder. Reproduced from Tomosawa, F., Noguchi, T., Tamura, M., 2005. The way concrete recycling should be. *Journal of Advanced Concrete Technology* 3, 3–16.

Fig. 5 Operation of a screw mill. Reproduced from Tomosawa, F., Noguchi, T., Tamura, M., 2005. The way concrete recycling should be. *Journal of Advanced Concrete Technology* 3, 3–16.

Fig. 6 Operation of a wet scrubber/levigator. Reproduced from Tomosawa, F., Noguchi, T., Tamura, M., 2005. The way concrete recycling should be. *Journal of Advanced Concrete Technology* 3, 3–16.

NA, however, in most other countries, the refinement is carried out partially. The output from recycling when partial refinement is achieved, would consist of a coarse aggregate containing residual mortar on its surface mainly (>5 mm) and a fine aggregate crushed into fine particles (typically less than 5 mm). Due to the differing sizes and constituents, these two materials in the recycled concrete stream differ in properties significantly. Most of the coarse portion would consist of rock/aggregate with mortar content amounting to 15%–30% by weight, while the fine portion would have cement mortar particles and fine aggregate coated with cement mortar. This article discusses the properties of the mixed stream and each of the two constituent material streams.

Fig. 7 Mixed recycled concrete.

Mixed Recycled Concrete

As the mixed recycled concrete has two distinctively different materials mixed together, their proportion would determine the properties of the mixed material stream. [Fig. 7](#) shows an image of mixed recycled concrete.

Properties of mixed recycled concrete

Mixed recycled aggregate from a typical crushing process would contain 55%–73% of coarse recycled aggregate, 25%–47% of fine recycled aggregate, and 0%–2% of other contaminants.

Applications of mixed recycled concrete

As a mixed material, mixed recycled concrete can be used for a more generic purpose, where the specific properties of the constituents do not affect the application significantly. Therefore, this mixed recycled concrete is used as a filler material, mostly to cover road bases. As a road-base material, recycled concrete replaces gravel and rock and is used as a filler. While this application makes the recycling process very simple and less costly, it is considered as a downcycling option. The simplicity to the recycling process comes from the fact that the coarse and fine recycled concrete does not need to be separated and the material can contain a high degree of impurities and still be considered acceptable for the application.

Coarse Recycled Concrete Aggregate

The separated out coarse recycled concrete has a high representation of the coarse NA used to manufacture concrete.

Properties of coarse recycled concrete

Physical properties

The main difference that is physically observable between coarse RCA and NA is the presence of residual mortar originating from the parent concrete, which recycled concrete was originally a part of. It is observed that the old adhered mortar present on the aggregate makes the coarse RCA particles (1) less dense, (2) inhomogeneous, and (3) porous ([Poon et al., 2004](#)). The density of coarse recycled concrete may vary from 2200 to 2400 kg/m³ compared with the density of NA, which is observed to be approximately 2600–2650 kg/m³ ([Poon et al., 2004](#)). The reason for the difference in density is attributed to the porosity of the aggregate, which results in a lighter structure and higher water absorption.

The dimensional and surface characteristics of recycled concrete contribute to higher water absorption, in addition to the porosity resulting from residual mortar.

Comparison of surface texture, which measures the degree to which the particle surfaces are polished, dull, smooth, or rough, depends on the hardness, grain size, and the pore characteristics suggesting that coarse recycled concrete has a weak surface with microcracks compared with the surface of NA ([Tam and Tam, 2007](#)). The texture of recycled concrete is observed to be rough and consist of a granular texture due to adhered mortar, which contributes to higher water demand ([Etxeberria et al., 2007](#)).

Coarse recycled concrete is considered to have a heterogeneous distribution of attached mortar, with larger particles carrying less of mortar compared with their size. Therefore, coarse recycled aggregate with larger particle sizes tend to be less water absorptive compared with smaller particles.

Roundness, which measures the relative sharpness or angularity of the edges and corners of a particle, is largely controlled by the strength and abrasion resistance of the parent material ([Neville, 2011](#)). Coarse recycled concrete is observed to be more angular compared with round-shaped natural coarse aggregate and hence demands more water ([Behera et al., 2014](#)).

While some researchers argue that the presence of residual mortar makes the aggregate surface weak and brings inferiority to any material that contains it, some argue that having residual mortar can be viewed as a complementary inclusion, especially when it is used as an aggregate replacing NA in concrete. This is because RCA brings additional mortar to the new concrete.

Mechanical properties

As a composite material with multiple phases, the properties of the recycled concrete are affected by (1) the characteristics of the aggregate, (2) the bond between the aggregate and the mortar, and (3) the characteristics of the mortar. Therefore, the mechanical properties are discussed considering the above three phases.

(1) Characteristics of the aggregate

The toughness of the aggregate is an important parameter and it is indicated by the impact value and the crushing value. Research has highlighted the importance of evaluating the strength characteristics of coarse recycled concrete, especially when it is used as a constituent material in concrete and correlation is observed between the aggregate crushing value and the strength of the aggregate. This is due to the fact that the adjustments required for the mortar mix may not be necessary if the aggregate has considerable strength (Butler *et al.*, 2013). The concretes produced with varying quality and hence strength of coarse RCA have found to have different tensile strength, modulus of elasticity, and energy at rupture, despite the adjustments in the concrete mix to have the same compressive strength (Butler *et al.*, 2013).

The surface texture and shape of the aggregate affects the strength of concrete by contributing to differing levels of bond with the mortar (Neville, 2011). Generally, a rougher texture of the aggregates results in a larger adhesive force between the particles and the cement matrix; whereas larger surface area of angular aggregate allows a larger adhesive force to be developed. The flexural strength of concrete is observed to be more affected by the texture and shape of the aggregate than the compressive strength. While the physical properties of aggregate have some influence on the strength of concrete, the effect due to the mechanical strength of the aggregate is quite significant (Neville, 2011).

(2) Bond between the aggregate and the mortar

The interlocking of the aggregate and the old mortar occur due to the surface roughness of the aggregate. The retention of residual mortar following the crushing operation is identified to be higher when the bond between the aggregate and the parent concrete is stronger (Behera *et al.*, 2014). It is identified that the strength of the aggregate and the compressive strength of the parent concrete would influence the modulus of rupture of the concrete due to the strength of the bond formed between the aggregate and the old mortar (Butler *et al.*, 2013).

(3) Characteristics of the mortar

The strength of the cement mortar attached to the recycled concrete has been observed to affect its strength directly as it is a significant proportion of the material. It is identified that the amount of residual mortar in RCA depends on the initial mortar content, the mechanical properties of the initial mortar, and the mechanical quality of the transition zone at the interface between the initial aggregate and the cement mortar (Belin *et al.*, 2013). Therefore, if the recycled concrete is used as a constituent material in concrete, it is advisable to study the source and characteristics of the parent concrete, both in terms of aggregate quality and mortar quality.

Applications of coarse recycled concrete

As a road-based material (in mixed form)

Currently, coarse recycled aggregate (sizes > 5 mm) is mostly used as a road-base material. As a filler for road-bases, coarse recycled aggregate is used as a part of the mixed recycled concrete stream. Using it in the mixed form, replacing natural rock as filler, is considered a downcycling option. On the other hand, when used as filler, the material remains mixed with the natural gravel or rock on the original surface being filled. The environmental risks associated with having recycled concrete mixed together with natural soil and rock in a submerged condition at ground level or underground, such as leaching, are to be explored yet and are being studied.

As a constituent material in concrete

Use of RCA substituting the NA in structural concrete is a preferred upcycled solution, as it has multiple advantages. Firstly, the resource value of the material is recovered and secondly, the material can be circulated in a closed loop. Thirdly, extraction of NA can be avoided, conserving natural, nonrenewable resources.

Coarse aggregates typically amount to 60%–75% of the volume of concrete, and their properties greatly affect the durability and structural performance of concrete (Behera *et al.*, 2014). Therefore in considering to replace the coarse aggregate portion of concrete with an alternative material such as recycled aggregate, it is important to consider the basic functions performed by aggregates in concrete. Aggregates, when used in concrete, (1) act as an economical filler in the concrete, (2) bring volume stability to concrete, and (3) bring durability properties to concrete (Neville, 2011) and any material replacing is expected to perform these functions.

When coarse recycled aggregate is used as a constituent material in concrete, it replaces NA fully or partially. If the aggregate is recycled employing a refinement methodology and the resultant coarse aggregate is similar to NA without the presence of residual mortar on the surface, the level of replacement of NA is high. However, if the aggregate is recycled using a typical crushing process, the residual mortar present on the surface of the aggregate makes it different to NA, so the manufacturing method or ingredients of

Fig. 8 Cross-section of a low-strength (30 MPa) concrete cylinder made with recycled concrete.

the new concrete needs to be modified to account for the difference in the properties of the aggregate. The identified ways to account for this change are (1) use of modified methods to prepare the coarse recycled concrete as a constituent material in concrete, (2) use of modified mix design methods to prepare the mortar phase of new concrete, and (3) use of modified ready-mix concrete manufacturing methods in producing concrete.

Several countries have developed guidelines for using coarse recycled concrete in concrete. Countries such as Japan have provided several options to use RCA based on their level of refinement, whereas other countries who deal with partially refined RCA have used several strategies to account for the changes that could come with using an alternative material in concrete. Considering the fact that recycled concrete could pose risks on the new concrete produced, the guidelines depicting the use of RCA often limit its use by imposing limits on the rate of replacement in concrete applications, limits on the types of applications (e.g., nonstructural applications), and limits on the level of strength categories it can be used for (e.g., low-strength applications). There are guidelines and standards developed across the world enabling grading of the recycled concrete and then diverting to recommended practices. [Fig. 8](#) shows a cross section of a low-strength (30 MPa) concrete made with coarse RCA, with some aggregate particles showing residual mortar.

Fine Recycled Concrete Aggregate

Fine recycled concrete is typically the portion that is less than 5 mm after the impact crushing process of concrete waste. This consists of fine hydrated cement particles in the crushed old mortar and fine aggregates in the old mortar.

Properties of fine recycled concrete

Similar to the coarse RCA particles, the fine RCA particles will also have the original fine aggregate with residual mortar attached to it, in addition to its containment of hydrated cement fines. It is observed that the residual mortar content attached to the original aggregate particle is heterogeneous based on its size. The amount of mortar attached to the fine fraction (33%–55%) was greater than that attached to the coarse fraction (23%–44%) as observed by [de Juan and Gutiérrez \(2009\)](#). Therefore, the amount of mortar and cement in the fine RCA stream tends to be higher than that in the coarse aggregate stream.

Applications of fine recycled concrete

There are several applications for fine recycled concrete identified in research. They are:

- (1) Use of FRCA replacing fine aggregate in concrete

Inclusion of fine RCA replacing fine NA has been studied by several researchers. While some researchers state that this is a complementary addition to the concrete if water absorption could be managed using appropriate quality control methods ([Dosho, 2007](#)), there are arguments against the replacement of fine aggregate with fine RCA mainly quoting the reduction of compressive strength ([Yang et al., 2008](#)).

It is argued that use of FRCA up to 30% does not affect the compressive strength of concrete ([Evangelista and de Brito, 2007](#)) and experimental investigations have suggested the strong possibility of the use of FRCA in concrete to yield high performance, even exhibiting behaviors similar to high-performance concrete ([Evangelista and de Brito, 2013](#); [Evangelista et al., 2015](#)).

- (2) Use of FRCA in precast concrete products

Another possible application for fine RCA is to use them in precast concrete products manufacturing, following a wet grinding process [Dosho \(2008\)](#).

- (3) Use of FRCA in clinker manufacturing

Inclusion of a large amount of hydrated cement provides the ability for fine RCA to be used in clinker manufacturing, which is a process step in cement manufacturing. Fine RCA can be used as an additive and it has been observed that adding such improved the burnability of the cement raw meal without negatively affecting the cement clinker properties ([Galbenis and Tsimas, 2006](#)).

Challenges and Opportunities – Recycled Concrete

Challenges in Using Recycled Concrete

Some of the main challenges in using recycled concrete in up cycled options, such as its use as a constituent material in concrete include complexities that could arise due to receipt of material from different origins, including different demolition sites and from construction applications using different materials. In addition to that, the use of material from demolition waste poses challenges due to contamination. Therefore, in diverting recycled concrete to an upcycled solution where producing a waste-derived, homogeneous material is a requirement, the following poses challenges considering the quality of the source material.

- (1) Differing compositions due to inclusion of aggregates and mortars coming from several sources and hence the differences in type and strength of the constituents
- (2) Uncertainty in the variability of critical parameters such as the strength
- (3) Unpredictability of contamination present in the materials

To overcome some of the challenges, tracking and control of the source concrete data are recommended as a proactive measure, and establishing a sound quality control system encompassing the entire supply chain is also required.

Opportunities for Using Recycled Concrete

In considering the solutions available to recover the maximum resource value of recycled concrete and divert it to an upcycled solution, use of recycled concrete in structural concrete seems to be the ideal option. This option enables recirculation of concrete waste in a closed loop and helps conservation of NA extracted for producing concrete.

To facilitate this, there are a number of explorations and advancements happening in research, which facilitates product and process developments to produce concrete, referred to as RCA, which resembles concrete made with NA and have equivalent properties. Most of the current advancements happening are in material characterization and improvement of the performance of the material considering production of recycled aggregate concrete RAC. The microscale studies of the material consider improvements to the interfacial transition zones formed between the coarse aggregate and residual mortar surfaces with the new mortar.

These advancements include:

- (1) Aggregate preparation methods

There are advanced methods considered for preparing the RCA such as presoaking the aggregate and coating the aggregate with pozzolanic materials. Presoaking is expected to saturate the particle, whereas fine pozzolanic materials is observed to act as a microfiller in filling pores, thereby making the aggregate particle stronger.

- (2) Design of mortar mixes in manufacturing RAC

Considering concrete as a multiphase material with coarse NA and mortar, replacement of one material, which constitutes a single phase, with another material, affects the integrated properties of the composite material. Therefore, redesign of the other phase, which is the mortar phase, is required to obtain the same properties of the original composite material.

The techniques adopted in mix design gathered from various researches include:

- (a) Addition of mineral (fly ash and slag) admixture and chemical admixture (plasticizer and super plasticizer) to counteract higher water absorption associated with RCA.
 - (b) Addition of cement and supplementary cementitious material to strengthen the mortar phase of the concrete.
 - (c) Design for higher strength and decrease water to cement ratio to account for higher variation associated with RCA.
- (3) New mixing methods to produce RAC

Tam and Tam (2007) suggested to adopt a two-stage mixing approach to produce RAC of improved quality, with a strengthened interfacial transition zone formed between the fresh mortar and the RCA. This mixing approach has also been observed to overcome the typical problems resulting from high water absorption and high porosity of RCA. A novel triple mixing process method was developed by Kong *et al.* (2010), where a surface coating is applied using pozzolanic materials to further improve the microstructure of the interfacial transition zones formed in the RAC.

Concluding Remarks

Concrete as the second most consumed material on Earth contributes to the equally large waste material stream – C&D waste. Concrete waste is either included in the construction waste stream as process waste or the demolition waste stream, as end-of-life products of a construction. Recycled concrete produced after separating out the concrete waste portion of C&D waste is mostly used as a road-base material nowadays. The main constituents of recycled concrete – the coarse aggregate, the fine aggregate and cement/mortar fines have immense potential to be used as a constituent material of concrete and in other products and forms that provide better value to the recovered material. While recycled concrete, being a waste material, poses challenges concerning homogeneity and inconsistencies to be used in concrete and other traditional products, the product design, characterization, as

well as processing technologies have been evolving in the last couple of years, enabling improved product performance. The destination researchers intend to reach is to allow possibilities for concrete to run in a closed-loop as a construction material, allowing iterative production, recycling, and reuse, and the journey to that destination has already commenced.

Reducing Waste in Circular Economy

Sandeep Goyal, LM Thapar School of Management, India and Institute for Competitiveness, Gurgaon, Haryana, India

© 2020 Elsevier Inc. All rights reserved.

Introduction

The global population has crossed 7 billion by 2018 and is expected to go beyond 9 billion by 2050 (Maassen and Altamirano, 2017). There is a rapid pace of urbanization which is creating a significant stress on the society and environment related to noise, air, water and soil pollution and increasing amount of solid and e-waste. The linear model of mass production and consumption is breaching the sustainability limits of the globe and taking the world closer to ecological disaster (Esposito *et al.*, 2015). Going by the current production and consumption patterns, people living on this earth will require two planet equivalents of natural resources to meet their consumption need by 2030. This demand will increase to three planet equivalent of natural resources by 2050. There is a need to make a shift from “take-make-waste” oriented linear economy towards “reduce-recycle-reuse” driven circular economy (CE) (Hower, 2016). Though in a state of infancy, there is an increasing realization among the global economies and companies towards adoption of sustainable products and consumption patterns. Going by the current rate of consumption and increasing disposable incomes, material consumption is expected to triple by 2025 (Bhutani and Arya, 2017). This calls for a paradigm shift from ‘produce-consume-dispose’ led linear economy to ‘reduce-recover-reuse-recycle-redesign-remanufacture’ led circular economy. During COP21 (2015 Paris Climate Conference), Karmenu Vella, European Union (EU) Commissioner for Environment, Maritime Affairs, and Fisheries stressed upon the role of CE in tackling climate change (Tse *et al.*, 2016). He highlighted how EU invested Euro 650 million for tackling the ecological imbalance and waste pile-up. Setting up a CE value chain is necessary to improve the overall production and consumption patterns. According to C40 Deadline 2020 research (see “Relevant Websites section”), it is required to reduce the carbon emissions from an average of 5 tons carbon-dioxide (CO₂) per capita to 3 tons CO₂ per capita by 2030 (EMF, 2018). CE is defined as the systemic focus on elimination of waste by adopting the recycling, reuse and repair paradigms (Bordoloi, 2016). CE is more about a new way of thinking towards a sustainable and cleaner tomorrow. It is not only about conservation of resources and restoration of ecological balance. It is rather an orientation towards “cradle to cradle” economy, which will lead to better growth and socio-economic equality for the people across countries (Esposito *et al.*, 2015). CE has moved beyond the humble origins of recycling and repair to widespread adoption in terms of sustainable value chains and business models. During 1990–2020, CE has moved up on the maturity curve beyond the focus on resource efficiency and sustainable production towards sustainable consumption. Both production and consumption patterns need to be addressed to drive the change on this planet. The idea behind circularity is to look at the conceptualization and value-chain of the products in terms durability, reuse and repair. Also, circularity stresses upon the optimal utilization of resources. For example, individual owned cars remain parked more than 80% of the time and the commercial space has an average utilization of only 40% of the time in Europe (Plastrick and Cleveland, 2018). One need to look at shared economy models to enhance the utilization of resources. According to noted researchers, waste has a significant value within but remains a waste as long as we consider it to be a waste (Himmelfab and O’Dea, 2015). As world is becoming inter-connected, geographic boundaries are fading away, global marketplace is taking shape with suppliers and consumers coming closer than ever (Hoekstra, 2018). This has created a situation where both suppliers and buyers need to recognize, align and work towards a cleaner tomorrow.

This article exemplifies how nations, cities, companies, and individuals can make a significant contribution in reducing waste by adopting CE practices. The article proceeds as follows. The first section defines CE. The second section highlights the need for making a shift from linear economy to CE. This is followed by a section explaining the challenges in going circular. The fourth section talks about business model typologies. The fifth section highlights the examples regarding adoption of CE approach by companies and nations. Finally, there is a conclusion section to summarize the role of CE in reducing waste.

What is Circular Economy?

According to Ellen MacArthur Foundation, CE is one that is restorative and regenerative by design and is all about an upstream solution that focuses on enhancing the natural capital, preserving the natural resources, and minimizing the waste generation (Shareable, 2018). The core defining element of CE is the “restorative use” of resources (Geisendorf and Pietrulla, 2018). CE stresses upon the active use and extended life-cycle of products, materials and resources in the economy as well as minimizing waste generation (see “Relevant Websites section”). CE is an intersection of economic and environmental aspects which marks a shift away from the linear economy. CE is gaining traction as a meaningful alternative to make a transition from continuous growth in production and consumption towards resource efficiency and ecological balance (Ghisellini *et al.*, 2016). CE involves steps for cleaner production orientation at company level, higher responsibility and awareness among producers and consumers, use of renewable sources, and push for recycling, reuse and repair oriented business models. CE focuses on creating an ecosystem which is restorative and regenerative by design. This implies setting up a value chain in which materials flow in a “closed loop” system rather than following a linear use and throw approach. Adoption of a CE approach yields benefits for the business and

environment in terms of lower costs, less waste and sustainable ecological balance. CE is looked upon differently by different people from implementation perspective. Ellen MacArthur Foundation (EMF) defines CE as an approach linked to resource efficiency, closed-loop supply chain, reverse logistics, low-waste production, industrial ecology, longer product life, and disruptive business models (Geisendorf and Pietrulla, 2018). According to research recommendations, adoption of CE approach can reduce the consumption of new materials upto 30% by 2035 and 50% by 2050 (Esposito *et al.*, 2015).

Why Need for Transition From Linear to Circular Economy?

The moot question today is that what we are going to leave for the future generations. Will they be able to sustain and survive considering the rapid environmental degradation and exploitation of resources? Are we going to create a better world for tomorrow or not? Certainly not, if we take into consideration the over consumption of resources, linear use and throw mind-set, consumption led marketing, ecological imbalance, and cities becoming garbage dumps. Everybody from government to companies to individuals needs to make a transition from linear consumption orientation to circular approach to create a better tomorrow (Goyal *et al.*, 2016). Refer to Figs. 1 and 2 for a comparative view of Linear Economy and Circular Economy.

According to World Bank estimates, cities globally produce 1.3 billion tons of solid waste annually. This is expected to reach 2.5 billion tons by 2025 (Shareable, 2018). Around 46 million tons (41.8 million metric tons) of electronic waste (e-waste) was produced in 2014 having an intrinsic material value of around USD 52 billion (Hoff, 2015). The e-waste volume is expected to reach beyond 60 million tons by 2020. USA and China contributed one-third of this e-waste in 2014 (Hoff, 2015). Major proportion of the consumables is getting into landfills every year due to lack of incentives for recycling, under-developed policy framework, dis-aggregated recycling setup, inefficient reuse and non-focused repair ecosystem. For example, India produced around 62 million tons of municipal solid waste (MSW) in 2016 with more than 81% of the same going to landfill sites rather than getting processed. India, being an extensive coal-use economy will have more than 225 million tons of fly ash by 2032 (Bordoloi, 2016). Till 2016, India was able to use only 38% of its fly ash in other activities like cement manufacturing, brick manufacturing, etc. India had more than 8.5 million end-of-life vehicles on the road generating huge amount of environmental pollution (Bordoloi, 2016). The number of end-of-life vehicles is expected to reach 22 million by 2022.

Adoption of CE approach can yield tremendous socio-economic and environmental gains for the countries. For example, one ton of recycled paper saves approximately 17 trees, 2.5 barrels of oil, 4100 kWh of electricity, 4 cubic meter of landfill and 31,780 litres of water over production of virgin paper from wood (Bhutani and Arya, 2017). One ton of recycled steel scrap saves 1.2 tons of iron ore, 0.7 tons of coal, 0.5 tons of limestone, 287 litres of fuel oil, and 2.3 cubic meters of landfill (Bhutani and Arya, 2017). According to a study by the University of Oklahoma, recycled steel reduces 97% mining waste, saves 75% of energy, cuts back 86% of air pollution and 76% on water pollution (Bhutani and Arya, 2017). Similarly, recycling of aluminum cans or replacing those with glass containers leads to significant reduction in waste going into land-fills.

Transitioning to a CE is a mandatory action needed to restore the social, economic and ecological balance (Hoekstra, 2018). At the same time, this is needed to safeguard the planet for the future generation. As per the current production and consumption trends in lineal economy, resources on this planet will not be enough to feed the people beyond 2050. Following are the major risks of continuing with a linear approach to design, manufacturing and disposal. *First*, linear use and throw approach has resulted in huge ecological imbalance - land, soil, air, and water. This has a cumulative effect on the physical and socio-economic well-being of the people. *Second*, more than 80% of the raw materials used in design and manufacturing of product offerings end up in landfill sites sooner or later thereby leading to growing volumes of waste going into landfills and creating ecological imbalance. *Third*, use and throw mind-set creates a scarcity of raw materials resulting in demand-supply gaps and cost overheads for the manufacturers and consumers. *Fourth*, linear consumption and discard approach forces the companies to focus on volumes driven value chain without any means of recycling or reuse. This restricts the scope for innovation in traditional companies leading to

Fig. 1 Linear economy. Source: Created by Author.

Fig. 2 Circular economy. *Source:* Created by Author.

hyper-competition. In this scenario, new entrants like Uber, Airbnb and Ola disrupted the industry dynamics by launching innovative shared economy business models. *Fifth*, countries are tightening the regulatory laws and policies to penalize the companies responsible for carbon emissions and waste generation.

Underlying Challenges in Adoption of Circular Economy

Adoption of CE is still in a stage of infancy due to multiple challenges like consumption oriented business models, antiquated public policies, lack of push by the governments in promoting circular strategies, and need for educating the businesses and individuals about the merits of CE.

Technology companies pose a major challenge by promoting “Consumption-led” business models. Take the example of mobile industry. Around 50 million tons of e-waste was generated in 2018 (Shenoy, 2018). More than 50% of e-waste was due to the rapid growth of personal devices like mobiles, laptops, computers, TVs and iPads. Only 20% of the e-waste gets recycled and remaining 80% goes into landfills every year. The total value of raw materials in e-waste was estimated to be more than USD 60 billion in 2018 (Bandela, 2018). This was higher than GDP of large number of countries globally.

An average person tends to change his/her mobile every one year and discards the existing mobile thereby contributing to an increasing stockpile of e-waste on this planet. The majority of the mobile manufacturing companies tend to focus on increasing volumes with new models and designs. There has been little focus on promoting the drive for recycling or refurbishing the obsolete mobile handsets. Both the consumers and producers need to change the mind-set from over-consumption led economy to sustainable consumption oriented economy.

The majority of countries lag in terms of designing waste conservation policies, building the right infrastructure for recycling industry, creating a sense of urgency for the companies and individuals as well as making provisions for giving incentives to the individuals and companies going circular. The volume of solid and e-waste has been increasing rapidly resulting in landfills and dumping sites around. For example, India produced around 62 million tons of municipal solid waste in 2017. This included more than 26,000 tons of plastic waste getting generated on daily basis. As per the current production, consumption and disposal trends, solid waste is expected to reach beyond 165 million tons by 2030 and 450 million tons by 2045 in India (Samaddar and Bandyopadhyay, 2018).

Multiple reasons are responsible for this growing challenge in developing economies like India. *First*, municipal infrastructure is obsolete with insufficient waste processing infrastructure in developing economies. This has led to increasing number of landfill sites across the cities. *Second*, there is a lack of clear government intent and policies to make the people and companies accountable for waste generation and segregation. This allows the companies to leverage political patronage for bypassing the waste, pollution and recycling norms and standards. *Third*, waste collection and segregation is still considered to be a menial job in countries like India thereby denying the socio-economic parity and respect for the people and the companies doing the same. Due to this, most of the companies and individuals lack interest and motivation in becoming a part of waste processing industry.

Understanding Circular Economy Models and Paradigms

CE involves action across three dimensions (Tse *et al.*, 2015). The *first* dimension involves undertaking actions and processes to reduce waste during the production and consumption processes. The *second* dimension involves propagating the “Servitization” approach where the focus shifts from product or asset based business models to service oriented ones. The *third* dimension involves extending the usable life-cycle of a product by recycling, reuse or repair. Going “Circular” is not just a case of incremental innovations but implies embracing real innovation and change in mind-set and business models (Edie Newsroom, 2016). Products should be designed for long-term use, ease of dis-assembly and ease of repair. Companies need to implement effective take-away and collection mechanism for obsolete products.

Fundamentally, there are five main CE business model typologies, which are being implemented by the companies globally (Riel, 2018; MEFD, 2016).

Circular Supply Chain Model

This involves making use of fully biodegradable, renewable and recyclable inputs across the supply chain. This makes the supply chain efficient and cost effective for the company, suppliers and customers. This model also included removing inefficiencies in the supply chain. This model is useful for companies having major carbon footprints or dealing with scarce commodities.

Resource Recovery Model

This includes recycling the product at end of life into diverse upscale product offerings thereby eliminates waste, creating alternate revenue streams and yielding environmental benefits. This model is useful for companies generating large volumes of by-product or companies yielding waste material which can be reprocessed cost effectively.

Product Life-Cycle Extension Model

This model relates to extending the life-cycle of products and assets by repairing, reconditioning, re-treading, re-marketing or re-manufacturing the used products and selling them in price conscious markets. This model is relevant for capital-intensive B2B (business-to-business) companies like industrial enterprises or B2C companies (business-to-consumer) having price-sensitive product offerings.

Sharing Platform Model

This model relates to launching a shared platform for sharing of assets, happy hours usage during low peak demand thereby increasing productivity and utilization. This model encourages collaboration among product users thereby ensuring demand-supply mapping and optimization of returns on under-utilized or segregates assets. This is applicable for all types of products and service offerings having under-utilization due to product ownership based usage. Companies like Uber and Airbnb spotted this opportunity and introduced innovative business models for car and home sharing respectively. During 2008–2015, Airbnb expanded its presence to more than 34,000 cities in 137 countries.

Product as a Service Model (PAS)

This model involves offering products on lease or pay-for-use. The companies adopting this model need to ensure product durability, reusability, and service excellence. From user perspective, PAS model eliminates the need for ownership to make use of any product. From supplier perspective, PAS model ensure optimal utilization of assets thereby replacing obsolescence and waste with long lasting efficiency and better revenue streams. This creates alternate revenue streams, better accessibility and availability for larger set of customers without the need for ownership. For Example, General Electric and Pratt & Whitney offer jet engines on rental basis. This model is applicable for companies offering expensive products to the market. This model works better for those products where better upgrade and maintenance is required.

Circular Economy in Practice

Country and Cities Level Examples

Countries and cities have started initiating a dialog with the industries to set up common goals towards sustainability and ecological balance. Cities globally are launching awareness drives and incentivizing the companies and individuals as per the behavior change orientation towards CE initiatives. Cities are redesigning their procurement policies and public institutions in accordance with circularity principles (Plastrick and Cleveland, 2018).

In 2013, Oslo city introduced public transportation buses powered by banana peels. This was a novel city level initiative, wherein residents in Oslo were asked to put the food waste in special green bags (Plastrick and Cleveland, 2018). This waste was recycled into biogas and used as a clean fuel for running the buses. This initiative was aimed at reducing the GHG (greenhouse gases) emissions from decaying waste. In 2002, San Francisco set up a target of “zero waste by 2020”. The actions involved converting city food waste into compost to be used by the farmers. The similar CE approach of converting food waste into fuel or compost has been adopted by many other European cities over the years.

In 2018, city of Ontario in Canada passed North America’s first Circular Economy law (Riel, 2018). This made it mandatory for producers and importers of electrical and electronic components to ensure recycling of e-waste rather than diverting the same to landfills. The companies in Canada started designing electronic components with ease of disassembly and recycling in accordance with the Ontario Law 2018.

Countries like USA and China transformed the waste collection, segregation and processing into a technology driven ecosystem providing respectable job opportunities to the people as well. According to Institute of Scrap Recycling Industries (ISRI), scrap industry in USA generated over 150,000 direct jobs and 323,000 indirect jobs in 2015 (Samaddar and Bandyopadhyay, 2018). In China, recycling industry generated 1.5 million direct jobs and 10 million indirect jobs (Samaddar and Bandyopadhyay, 2018). In India, metal recycling industry employed around 1.75 million people and contributed around 2% to the GDP.

Several developed economies especially the European nations initiated policy level actions to drive the adoption of CE approach (Bhutani and Arya, 2017). Sweden offered tax breaks for repair activities (50% cut on value-added tax) and passed the law that mandated electronic goods retailers to accept the same quantity of goods as sold by them for reuse or recycling. Similarly Japan and Netherlands announced strong CE legislations. China passed the Circular Economy Promotion Law (CEPL) in 2009 to promote the adoption of sustainable CE practices. According to Waste and Resources Action Programme (WRAP), UK CE ecosystem led to recycling of more than 75% of the solid waste by 2018.

Industry and Company Level Examples

Due to gradual push by the governments globally, companies have started providing correct labeling of products regarding the end of life. Also, companies have started setting up collection centers and providing reimbursements or monetary incentives to customers to encourage the collection of products reaching end of life (Bordoloi, 2016).

Dell introduced *2020 Legacy of Good Plan* in 2013. This plan called for an increased focus on enhancing the use of recycled material and minimizing e-waste by adopting the closed-loop supply chain and enhancing the useful life of plastics (Tse et al., 2015, 2016). The company recycled old computers and plastic bottles, which were being collected via “take-back” scheme and used those in the manufacturing of monitors and desktops. This resulted in significant cost savings and reduction in carbon emissions. CE orientation has given a tremendous boost to the brand image of Dell (Himmelfab and O’Dea, 2015).

Unilever launched Zero-Waste drive as a part of CE orientation in early 2000. The objective of this drive was to send across zero non-hazardous waste to landfill from the network of 240 factories in 67 countries (Himmelfab and O’Dea, 2015). The measures involved smart sourcing of raw materials, reusing and recycling manufacturing excess by composting or cross using those in other industrial chains. Zero waste orientation led to considerable cost savings besides create a positive brand image among the consumers as an environment friendly company.

PepsiCo initiated buy-sell drive and collaborated with different players for buying and selling used products. It undertook cross-farm collaboration to source slurry from Dutch and Belgium dairy and pig farms and used the same as natural fertilizer on their potato farms. The use of slurry reduced the need for chemical-based soil enhancers and associated carbon emissions (Himmelfab and O’Dea, 2015).

Similarly, P&G’s launched GARP (Global Asset Recovery Purchases) initiative where it started selling unusable fibers from Mexico based toilet-paper plant to the local companies for manufacturing low-cost roof tiles.

Coca Cola adopted circular packaging by cleaning and reusing glass bottles as well as recycling PET bottles and aluminum cans into upscale products. The company collaborated with partners like Ekocycle while introducing plant-bottle technology (Himmelfab and O’Dea, 2015). This technology was used by Coca Cola for creating recyclable PET bottles from agricultural by-products like sugarcane waste.

In Turkey, Frito Lay focused on composting while going for a circular business model. The company generated biogas and organic digestate by processing waste from potatoes, corns and broken chips. The company used the biogas for meeting up to 35% of the power consumption need of the manufacturing plant in Turkey. It converted digestate into compost and gave it to the local orchards for enriching soil of their farms.

Starbucks collaborated with Japanese contact lens manufacturer, Menicon for recycling coffee grounds into livestock feed (Himmelfab and O'Dea, 2015). Menicon used lactic acid fermentation technique to supplement the coffee grounds with nutrients and offered the same as cattle feed.

Telefonica introduced circular oriented culture in the company by taking up series of actions (Telefonica Website, 2018). First, it created purchase agreements with the suppliers showing clear preference for the suppliers making use of renewable resources and offerings products having least environmental impact. Second, it implemented a paperless invoice setup for its 53 million customers thereby saving thousands of trees per annum. Third, it created an ecosystem for recycling and reuse of e-waste generated by the company in the form of cables, batteries, tubes, papers, routers, customer telephones etc. It set up a digital waste management system across all its offices. Fourth, it started branding itself as an environmental conscious and ecological friendly company. The company incentivised the customers by facilitating the reuse or recycling of their old mobiles phones while going for a new one.

Conclusion

There is a well-placed belief today that circular thinking can transform the lives of everybody on earth and will make the planet liveable for future generations. It is important to bring a behavior change orientation among the stakeholders by promoting system thinking, putting price on the negative externalities and change perceptions regarding the true value of natural resources (Bordoloi, 2016). As per calculations, every ton of discarded textile getting reused can save up to 20 tons of CO₂ and every 1000 tons of used textile collection and processing can create at least 7 direct and 15 indirect jobs (Bordoloi, 2016). Similarly, circular approach in the food industry can help reduce hunger, social inequality and generate millions of jobs in up cycling initiatives. In electronics industry, push towards the end of life for electronic goods by recycling, repair or reuse can generate millions of jobs in e-waste industry besides reducing the huge dumping of e-waste. Plastic is one of the major contributors to solid waste and ecological imbalance. Minimizing the use of plastic via government legislation and processing the discarded plastic bags into construction of tar roads can create a tremendous ecological impact. As per calculations, every kilometer of road being laid out using CE approach utilizes equivalent of million plastic bags, saving around a ton of asphalt and cost savings by 8%.

One does not need to be a rocket scientist for circular orientation. The companies can start identifying and implementing circular thinking in their day-to-day operations across the value chain. How can we encourage use of renewable resources? How do we encourage water and electricity conservation? How can we enhance the usability of what we consume and what we produce? How do we create a recycle value chain? How do we encourage the circular thinking and behavior among the employees? These are some of the questions which individuals and companies need to evaluate every day and take appropriate actions. The whole idea of CE is to look at products from regenerative or restorative perspective. "Use and Throw" and "End of Life" mind-set need to be replaced by recycling, reuse and repair of product offerings thereby eliminating the waste through circular value chain as well as innovative business models (MacArthur, 2013). Finally, no drive can be successful without the active role and contribution of the government. It is mandatory for the governments globally to design and implement strong policies and regulations that will ensure the right focus and attention towards circular orientation by all the stakeholders (companies, individuals, institutions etc.).

Subtractive Manufacturing

During last decades, significant progresses are developed in the industrial sector in the field of conventional subtractive operations. Here, conventional machining operations occupied and dominated the entire manufacturing sector. New advancements in manufacturing of the machines and tools used for cutting are mostly led by the conventional machining operation. Along with it, it also showed a new pathway for manufacturing of product through an ultimate process planning systems including certain small variation during selection of cutting tool, coolant, lubricant and using the optimum parametric setting. The new technology involved in the subtractive processes controls the machining time, adaptively, and helps in reducing the repetition and error generation on the surface quality. Machining process is one the oldest and versatile method used in the subtractive manufacturing of the today's generation products and services. It has numerous categories depicting the ways to achieve the desired geometry by full filling all dimensional, mechanical, and metallurgical requirements. The broad classification of the conventional machining operation in term of subtractive machining is shown in the Fig. 1.

The critical improvement is seen in conventional machining techniques during manufacturing of complex and integrated shape and size of components in industry. The adoption of conventional machining operation critically depends on the machine performance and machinability aspects. These involves cutting forces, temperature generation at tool-workpiece interface, tool life and surface integrity (Arrazola *et al.*, 2013). The fundamental needs of machining and outcomes of the machining process are shown in Fig. 2. Its involves input parameters, machining techniques, process planning, machine and machine tools to get the desired product or outputs in terms of minimal waste of billet, with high tool life in an efficient and convenient way.

Grinding

Grinding is an abrasive machining process that uses a grinding wheel as the cutting tool. The chips formed during operation are mostly microscopic or in powdery formed. The removal of the materials occurred by means of ploughing and shearing action (Malkin and Guo, 2008). Through grinding operation very close tolerances with high precision and good quality of the surface can be achieved during manufacturing of the components. Grinding operation needs a higher amount of specific energy, resulting high heat generation that increases the machining zone temperature and affects product characteristics (Pederson, 2004).

Therefore, the selection of the grinding wheel materials is very important, most of the case SiC abrasive are the major choice in the industry (Jackson and Hitchiner, 2011). Mostly the heat generates and the friction occurred during grinding operation is reduced through minimum quantity cooling and lubrication method (Mao *et al.*, 2013). Choi and Eastman used a nano particles

Fig. 1 Classification of conventional machining operation.

Fig. 2 Approach executed during machining process. Reproduced from Arrazola, P., Özel, T., Umbrello, D., Davies, M., Jawahir, I., 2013. Recent advances in modeling of metal machining processes. *CIRP Annals* 62 (2), 695–718.

fluid medium to enhanced thermal properties. Kalita *et al.* (2010) reduced the forces and friction generation at the wheel wear through using the MoS₂ with paraffin and soybean oil. Mao *et al.* (2013) used deionized water during grinding operation along with Al₂O₃ nanoparticle. This reduced the grinding force and temperature by improving the surface finish of the surface. Setti *et al.* (2015) studied the behavior of the wheel at different environment condition of grinding operation during grinding Ti-6Al-4V. The changes in the formation of the chips are also being studied. From Fig. 3, it is found that the high temperature formation leads to the creation of the wear flats on the surface of the wheel. The application of nanofluid reduces the temperature and dislodging of the gathered chip particle from the pores preserves the wheel conditions and thus reduces the wear flats.

The formation of the chips reveals that during dry and wet machining larger size of chip are produced but some time spherical shape of the chips is also formed during wet grinding. The cluster and fractured chips types of chip produced because of the chemical reaction between Al₂O₃ and titanium alloy as shown in Fig. 4.

Fig. 3 Morphology of the grinding wheel at different cutting condition. Reproduced from Setti, D., Sinha, M.K., Ghosh, S., Rao, P.V., 2015. Performance evaluation of Ti-6Al-4V grinding using chip formation and coefficient of friction under the influence of nanofluids. *International Journal of Machine Tools and Manufacture* 88, 237–248.

Rabiei *et al.* (2015) studied the friction coefficient, forces, surface morphology and surface roughness of CK45 and S305 steel during grinding operation with aluminum oxide wheel. The cooling condition considered during machining were dry, fluid and MQL cooling. It revealed that MQL machining techniques shows better results by decreasing the grinding forces and friction coefficient of the steels. Fritsche and Bleicher (2016) studied the dynamic behavior of the grinding wheel. In this sensor are integrated in the grinding wheel to know the deformation and stiffness. Tyagi *et al.* (2017) studied the dressing and truing techniques to achieve higher productivity. Dressing is required to maintain the sharpness and protrusion. While truing regains the shape of the grinding wheel which diverted because of the deformation. The concentricity of the wheel with principal bore can be made aligned with truing.

Turning

Turning is a machining process in which a cutting tool, typically a non-rotary tool bit, describes a helix tool path by moving more or less linearly while the workpiece rotates. Turning can be done manually, in a traditional form of lathe, which frequently requires continuous supervision by the operator, or by using an automated lathe. In turning material is removed in the form of chips. Most of the research had been made to find out the optimum process parameter to achieve a better machinability of the material. Asiltürk *et al.* (2016) Optimized the process parameter to accomplished a better surface quality of the Co28Cr6Mo medial material. The optimum setting founded was 318 RPM, 0.1 mm/rev feed, 0.7 mm depth of cut and 0.8 mm of tool nose radius. Chew *et al.* (Nee *et al.*, 2018) also studied surface roughness of the Co28Cr6Mo medial material through the differential evolution

Fig. 4 Chip formation at different grinding conditions. Reproduced from Setti, D., Sinha, M.K., Ghosh, S., Rao, P.V., 2015. technique (DE). It governs an algorithm that is simple fast and population based developed by [Storn and Price \(1997\)](#). The convergence profile of the surface roughness in terms of generation is shown in the [Fig. 5](#). The quality of the surface formed after machining increase the value and demands of production of the product ([Celik et al., 2017](#); [Yan, 2009](#)). The surface roughness studied portrays the fatigue strength, creep, wear and corrosion resistance of the machined surface. Therefore, it is necessary to control the factors affecting the surface roughness. A controlled surface roughness is achieved at a lower cutting speed and feed. Since increase in the tool wear with the cutting speed and feed aggravated surface roughness ([Celik et al., 2017](#)).

The Chatter produced in the tool during turning operation lead toward the inaccuracy of the machining and detritions in the cutting inserts. So the study had been made to reduce the chatter formation by changing the process parameter or through some new techniques. Some of the measuring instrument of signal processing technique used to detect the chatter such as dynamometers ([Kumar and Singh, 2018](#); [Toh, 2004](#)), multi-sensors ([Kuljanic et al., 2008](#)) and ammeters ([Soliman and Ismail, 1997](#)). Some other methods used by the researcher to suppress the tool chatter are piezoelectric actuation ([Albizuri et al., 2007](#)) active structural control ([Dohner et al., 2004](#)), magnetic bearing ([Chen and Knospe, 2007](#)), ultrasonic elliptical vibration ([Ma et al., 2011](#)) and spindle speed variation technique ([Wu and Chen, 2010](#); [Hajikolaie et al., 2010](#)). The wear of the cutting tool also depends upon the cutting parameters. The tool wear differs for CVD and PVD coating of tungsten carbide cutting tools. The tool wear increases with increase in the cutting speed for both CVD and PVD coated cutting tool. Tool wear increases because high cutting speed aggravate the cutting temperature during machining, since the materials possess low thermal conductivity. Also the area of the tool cutting edge and chips surface reduced increases the cutting temperature that accelerate the tool wear ([Astakhov, 2007](#); [Gorczyca, 1987](#)). The tool wear is more in CVD coated cutting tool as compared to the PVD cutting tool. This due to the

Fig. 5 Surface roughness DE convergence profile. Reproduced from Celik, Y.H, Kilickap, E., Guney, M., 2017. Investigation of cutting parameters affecting on tool wear and surface roughness in dry turning of Ti-6Al-4V using CVD and PVD coated tools. *Journal of the Brazilian Society of Mechanical Sciences and Engineering* 39 (6), 2085–2093.

chemical composition, the carbon percentage is high in CVD coated i.e., 32.13 wt% and also the presences of some other element such as oxygen and chlorine fascinates the reduction in the tool wear. The SEM images [Fig. 6](#) also justify a higher wear rate of CVD coated carbide cutting tool as compared to the PVD coated cutting tool. The higher cutting parameter effects the cutting temperature, pressure and increases the chances of chemical reactivity between the cutting tool and the workpiece, lead the development of tool wear in-terms of adhesion, dissolution and diffusions ([Sun et al., 2015](#); [Coppini et al., 2018](#)).

Milling

Milling is the process of machining using rotary cutters to remove material by advancing a cutter into a workpiece. This may be done varying direction on one or several axes, cutter head speed, and pressure. Milling covers a wide variety of different operations and machines, on scales from small individual parts to large, heavy-duty gang milling operations. It is one of the most commonly used processes for machining custom parts to precise tolerances. In milling operation, the material is removed from the workpiece by providing minimum feed rate with high speed rotation of the milling cutter. The cutting parameters are the most influencing factors that affect the responses. The cutting parameter can be spindle speed, depth of cut, feed rate, materials of the workpiece and tool, uncontrolled parameter such as uneven disturbances and machine errors ([Mahesh et al., 2015](#); [Jang et al., 1996](#)). The output responses such as tool wear, surface roughness, cutting force etc., have to be considering in achieving a better machinability of the materials. Surface responses are mostly affected by the feed rate ([Wang and Chang, 2004](#)). Surface roughness and waviness are the irregularities appeared on the machined surface due to the vibration, deflection, human and machined errors ([Arias, 1983](#)). Researcher suggest that it can be control through various theoretical approach ([Quintana et al., 2010](#)), analytical approach ([Mansour and Abdalla, 2002](#); [Alauddin et al., 1997](#)), experimental investigation through orthogonal array and response surface approach ([Chang et al., 2007](#); [Coker and Shin, 1996](#); [Gologlu and Sakarya, 2008](#); [Dhokia et al., 2008](#)). In some case the optimum cutting parameter had been achieved through various neural network, genetic algorithm, fuzzy logic and neural fuzzy method ([Tsai et al., 1999](#); [Benardos and Vosniakos, 2002](#); [Brecher et al., 2011](#); [Ali and Zhang, 1999](#)).

Tool wear accelerate by the size and thickness of the chips, the mechanics of material removal rate depend upon the ploughing region where the materials deform plastically, due to this high friction and stress generated between the cutting tool and the workpiece ([Teng et al., 2018](#)). This weakens the cutting edge by acquiring the highest load in the tip portion of the cutting edges. Some of the tool wear occurred due to the catastrophic failure of the cutting tool during milling operation ([Li et al., 2011](#); [Tansel et al., 1998](#)). [Tansel et al. \(2000\)](#) concluded that fatigue and stress generation and chip clogging breakage of the cutting edge are the most important factors considered for reducing the life of the cutting tool. Higher cutting force generation also reduces the sharpness of the cutting edge and decreases the life of the cutting tool. [Rahman et al. \(2001\)](#) observed that tool wear occurred in the major and minor cutting edge of the tool was due to the non-uniform chip and the adhesion of chip on to the surface of cutting edged because of the high cutting temperature and pressure generated at higher cutting force. [Filiz et al. \(2007\)](#) found that

Fig. 6 Flank wear at different cutting speed with feed 0.104 mm/rev and depth of cut 1.5 mm. Reproduced from Celik, Y.H, Kilickap, E., Guney, M., 2017. Investigation of cutting parameters affecting on tool wear and surface roughness in dry turning of Ti-6Al-4V using CVD and PVD coated tools. *Journal of the Brazilian Society of Mechanical Sciences and Engineering* 39 (6), 2085–2093.

during micro-milling of copper the tool failure of the tungsten carbide was observed due to the abrasion wear. The micro chipping action during machining blunt the edges by diffusion mechanism, where the workpiece materials diffuse into the WC-Co binder with respect to the adhesion effects (Imran *et al.*, 2014). Kiswanto *et al.* (2014) studied the surface roughness and burr formation during miniaturized micro machining operation by varying spindle speed and feed rates. It is observed that surface roughness is affected by feed rate and machining time. Wang *et al.* (2005) justified that tool diameter and spindle speed increases surface roughness. The improvement of surface quality can be made by increasing the structure and stiffness of the cutting tool, since it's reduces the vibration and chatter. Vazquez *et al.* studied the surface roughness behavior by varying the spindle speed, depth, feed per tooth, depth of cut per pass and the coolant. It is observed that surface roughness of the aluminum and copper is affected by feed per tooth and coolant application (Vázquez *et al.*, 2010). Whereas, Jin *et al.* (2009) observed that burr size and surface roughness increase due to the variation in lower feed per tooth and cutting edge radius. Hashimura *et al.* (1999) divides the formation of burr by its milling location, mechanism and shapes i.e., entrance burr, exit burr, side burr and top burr. Litwinski added the bottom burr formation concept for micro end milling operation (Litwinski *et al.*, 2006), as shown in Fig. 7.

The feed is linearly proportional to the height of the burr results in decreasing of the tool wear (Lee and Dornfeld, 2005). The radius of the milling cutter and the axial depth of cut affect the top burr formation (Chen *et al.*, 2012). Chu and Dornfeld (2005) found that burr height is influence by the uncut chip thickness and radius of the cutting edge. Biermann and Steiner (2012) found that top burr formation is also affected by the lubrication method and feed per tooth. Top types burr was formed on the top surface of the workpiece. The quality of the machined surface became poor due to the formation of top burr. Kiswanto *et al.* (2014) revealed for the experimental study that, the top burr can be minimized, refer Fig. 8, if optimizing the spindle speed and feed rate.

During the burr formation study, the size of the burr i.e., the width and length of the burr was measured as shown in Fig. 9. It is observed that an uneven burr formation is formed in the micro channel also it's facilitated along the cutting process. But some detachment or the dissipated burr formation is formed due to the formation of built up edge. The burr size varies according to the tool wear which occurs due to the chipping action at the tool edge as shown in Fig. 10.

Now-a-days, the sheet metal manufacturing has become a challenges due to the use of advanced high strength steel (AHSS) as blanks. Most of the automotive industry used this AHSS for the convenience safety requirements and manufacturing of light weight vehicle (Mackensen *et al.*, 2010; Kleiner *et al.*, 2003; Rahmaan *et al.*, 2017; Scales *et al.*, 2016; Bai and Wierzbicki, 2010, 2008; Papisidero *et al.*, 2015; Ubhayaratne *et al.*, 2017; Shang and Daehn, 2011; Seth *et al.*, 2005; Choomlucksana *et al.*, 2015). (Fig. 11).

Advancements in Subtractive Manufacturing

Subtractive manufacturing defines the formation of physical shapes by removing the material in the form of chips, burs, slices, etc. Generally, during the production of huge number of product, formation of co-ordination between various involved process parameters is a hurdle for rapid production in the industrial sector. Therefore, the recent studies in the field of subtractive machining are advance in the field of analytical modeling and finite element simulation. Yue *et al.* (Liu *et al.*, 2018) studied the

grinding pattern during correction made by grinding operation of rail profile. The new designed profile reduced the rail's maintenance time by increasing the service life. In this study the analytical model is developed using some of the wheel characteristics such as feeding feed, rotational speed and pressure applied to the rail. An algorithm developed to recognize and generate the grinding pattern. It is validated through the grinding quality and error in the rail profile as shown in [Fig. 12](#). [Azarhoushang et al. \(2018\)](#) observed that by grinding Si₃N₄ using laser assisted grinding process the material removal rates increased. This reduction is achieved due to the development of induced lateral cracks on the surfaces of silicon nitrides ceramics as shown in [Fig. 13](#).

[Agrawal and Patil \(2018\)](#) developed a new cutting approach by using green cutting fluid. The effect of surface roughness and tool wear during turning of M2 steel with minimum quantity lubrication using aloe Vera oil as cutting fluid are studied. The comparison is made with conventional cutting fluid. Results revealed that, surface roughness improved by 6.7% and the tool wear is lowered by 0.14%. [Pathak et al. \(2018\)](#) optimized the cutting parameters through taguchi fuzzy logic during turning of AISI A2

Fig. 11 Edge chipping during machining operation. Reproduced from Kiswanto, G., Zariatin, D., Ko, T., 2014. steel with carbide cutting tool. Since A2 steel is mostly used in making of forged dies, punch and machine tool parts. Detection of optimum setting for cutting such types of metal is important. During any subtractive machining operation, the reduction and controlling of residual stress is a difficult task. [Il et al. \(2018\)](#) experimentally obtained the internal temperature generates during milling of Al2024-T3 workpiece. Afterwards, it has been found that the residual stress using X-ray techniques and developed the relationship between the cutting parameter and workpiece internal temperature. Chatter is another important factor need to be control during subtractive machining. Deniz and Yusuf used CNC ([Aslan and Altintas, 2018](#)) system real time data for detection of on-line chatter using Fourier spectrum of drive motor current command. They used the frequency response function and eliminate the forced vibration components to detect the presence of chatter during milling operation. [Helo and Hao \(2017\)](#) used the cloud manufacturing system for sheet metal operation. [Li et al. \(2017\)](#) used a magneto-rheological fluid during bidirectional pressure forming on sheet metal. [Luksaz et al. \(Bohdal et al., 2018\)](#) performed 3D finite element modeling of sheet metal blanking operation to analyzed the contact friction, constitutive damage, dynamic effects and mechanical coupling during deforming 1018 steel. [Table 1](#) briefly summarizes the various activities done to hybridize the conventional manufacturing systems.

Computer Controlled Conventional Manufacturing

The computer numeric control (CNC) systems are the results of an increased demand of the military equipment, automobiles, smartphones and various other consumer products which exerted a huge pressure on manufacturing sector to maximize its resources. Therefore, the development of CNC machines is one of the means for manufacturing sector to deliver on increased demands. CNC technology brings together accuracy, precision and efficiency together, while delivering higher production rates. The highly sophisticated CNC machine tools found in various forms and diverse range in the field of manufacturing processing had very humble beginnings. Some of the earliest research and development work in this field was completed in the USA after the Second World War ([Bollinger and Duffie, 1988](#)). CNC machines are designed to be operated with minimum supervision and are more precise and consistent as compared to traditional machine tools ([Mattson, 2009](#)). This method of manufacturing is an appropriate choice for large volume production runs. The workflow of the hybrid additive subtractive manufacturing process, as shown in [Fig. 14](#), is similar to additive manufacturing workflow, but the significant difference is facility a subtractive manufacturing facility can be provided to manufacturing services to external customers which is less common in case of case of additive manufacturing.

This technique presents the significant opportunities for improvement and utilization of materials, For producing complexity and quality products. Advanced numerical control (NC), and computer-aided design (CAD), manufacture (CAM) and inspection (CAI) are playing a vital role to govern the process ([Flynn et al., 2016](#)). [Yampolskiy et al. \(2017\)](#) compared the additive and subtractive manufacturing from security perspective and outlines were given for analyzing attacks on or using additive manufacturing systems and subtractive systems. It was revealed that there is significant overlap concerning security, fundamental differences in the two manufacturing paradigms require a separate investigation of additive manufacturing security. [Flynn et al. \(2016\)](#) discussed the working of a system by combination of and subtractive processes within a single workstation and revealed that these type of techniques can play significant role in future for the improvement of These techniques present significant

opportunities to improve material utilization, part complexity, and quality management in functional parts as these methods facilitate the manufacture of internal, overhanging and high aspect ratio features with desirable geometric accuracy and surface characteristics. Fig. 15 shows the machine tool configurations that are emerging as preferred methods of integration for CNC machining.

Table 1 List of activities performed on hybrid conventional manufacturing

References	Workpiece and tooling	Techniques	Output measures	Findings
(Sofuoglu <i>et al.</i> , 2018a)	Hastelloy-X, Titanium alloy	Hot ultrasonic assisted turning (HUAT) FEM analysis	Average cutting forces, Effective stress, Cutting temperatures	In this hybrid machining approach of HUAT the cutting forces decreased by 50% as compared to conventional turning operation. The effective stress is reduced from 1600 MPa to 1250 MPa. The cutting temperature increases due to application of the external heat source
(Sofuoglu <i>et al.</i> , 2018b)	Hastelloy-X	Ultrasonic-assisted turning, Hot machining	Surface roughness, Chatter stability, Cutting tool temperature, Chip morphology	This paper combined the Ultrasonic assisted turning with hot machining. This method improves the surface roughness with a stable cutting depth. Whereas the tool life was reduced because of the higher cutting temperature. The variation in the chip thickness also reduced
(Sanchez <i>et al.</i> , 2010)	AISI D2 tool steel	Hybrid Minimum Quantity of Lubricant (MQL)-low temperature CO ₂ system, Biocut 3000 oil is used	Grinding wheel life, surface quality	The creation of durable tribofilm around the grits improves the sliding and lubrication action during grinding at extreme pressure conditions. The surface finish and force ratio is increase by 28%
(Sharma <i>et al.</i> , 2018)	AISI 304 stainless steel	Hybrid cutting fluid, blending Multi-walled carbon nanotubes (MWCNTs) with alumina-based nanoparticles into cutting fluid	Cutting temperature, Flank wear	This hybrid approach machining method reduced the flank wear by 11% and cutting temperature by 27.36%
(Jeng and Lin, 2001)		Metal rapid prototypes and molds fabricated using hybrid processes of selective laser cladding (SLC) and milling		By hybrid process of SLC and milling the accumulation of the powder and clad height is controlled accurately. The top surface was also found smooth through milling operation. By this process the layer thickness was reduced by significantly increasing the building time
(Nag <i>et al.</i> , 2018)	A359 aluminum alloy as base matrix and 2% B4C and 2% Al ₂ O ₃ as reinforcing particles	Tangential abrasive water jet (AWJ) turning of hybrid aluminum matrix composite fabricated by electromagnetic stir casting technology	Abrasive mass flow rate, surface quality, Reduction in sample diameter	This process reduced the tool wear. Nearly 30% in diameter reduction is observed. The olivine abrasive generated more internal cracks as compared to garnet

Hao *et al.* (2018) proposed the novel process planning algorithm for additive and subtractive manufacturing (ASM) system to remanufacture the disused part, the skeleton of the model was generated using the matching algorithm was developed for recognizing the different features between the initial model and the final model based on skeleton tree. Kerbrat *et al.* (2010) purposed the method for estimating the complexity of for subtractive and additive manufacturing to over the constraints at initial stage, i.e., designing of machine tools using CAD models. Li *et al.* (2018) proposed the 6-DOF hybrid additive-subtractive manufacturing (HASM) process model to overcome the limitations of additive manufacturing by integrating it with subtractive manufacturing. Newman *et al.* (2015) introduced the framework for process planning using the subtractive and additive technologies.

Hybrid Manufacturing

The hybridizations under this class of manufacturing basically involved the combinations of additive and subtractive manufacturing under a unified machine system. For instance, additive manufacturing in the form of laser cladding could be used to build up a metal form that, when cooled, is machined using traditional methods. Moreover, when laser cladding is used to build a metal form it needs to be machined with traditional machining. Fig. 16 shows the process build an overhang structure on a 2.5D and multi-axis deposition system. Coupled between the additive and the subtractive processes into a single workstation, the integrated process, or hybrid process, can produce a metal part with machining accuracy and surface finish (Liou *et al.*, 2007).

Zhang and Liou (2013) presented a parametric curve for automatic path planning hybrid manufacturing during material deposition and removal without the support structure. The parametric representation of STL-based layer geometry is presented to overcome the issue of complexity in multiaxis machining. Boivie *et al.* (2012) discussed the advantages of hybrid manufacturing for the production of high performance parts. Yamazaki (2016) discussed the possibility of developing the Hybrid Multi-tasking

Fig. 14 Software and control flow for the HASM process. Reproduced from Li, L., Haghighi, A., Yang, Y., 2018. A novel 6-axis hybrid additive-subtractive manufacturing process: Design and case studies. *Journal of Manufacturing Processes* 33, 150–160.

machine tool using Laser Metal Deposition functionality in addition to existing integrated turning and milling capabilities. It was concluded that Hybrid Multi-tasking machine tool with application examples and demonstrates possibilities and tasks for the next generation manufacturing, refer Fig. 17.

Karunakaran *et al.* (2010) discussed the features of both CNC machining (subtractive method) and Rapid Prototyping (additive method) and by combining these process for hybrid manufacturing. Müller and Wings (2016) discussed the advantages of hybrid manufacturing in context to the manufacturing of complex parts accuracy, less production time, and lower costs, etc. Skeebea *et al.* (2016) discussed various cases studies related to hybrid manufacturing and described the outlines some aspects of the future development of an integrated hybrid manufacturing system. Strong *et al.* (2018) discussed the advantages of hybrid manufacturing is required to achieve Geometric Dimensioning and Tolerancing (GD&T), surface finish and desired mechanical properties and also discussed the various challenges of traditional manufacturers to participate in the rapidly evolving supply chain of direct digital manufacturing (DDM).

Applications of a hybrid manufacturing process for fabrication of metallic structures. *Rapid Prototyping Journal* 13 (4), 236–244.

- CNC Milling

Milling-son *et al.* (Son *et al.*, 2009) 5-Axis CNC milling machines are essential in many industries ranging from aerospace to consumer-die-mold machining because they can deliver high machining accuracy with a spindle tilting capacity. They showed that the degree of over-constraint depends on machine size. We have designed a small hybrid 5-axis motion platform, the MIT-SS-1, refer Fig. 18, which can tolerate this over-constraint through a unique layout of axes. García Nieto *et al.* (2016) highlighted that

Fig. 17 Application example of a hybrid process by INTEGREX i-400 AM. Reproduced from Yamazaki, T., 2016. Development of a hybrid multi-tasking machine tool: Integration of additive manufacturing technology with CNC machining. *Procedia CIRP* 42, 81–86.

milling cutters are essential cutting tools used in milling machines to perform milling operations, which are prone to wear and subsequent failure.

Dave *et al.* (2014) reviewed a paper that showed various papers related to Portable Milling Machine. They included different types of portable milling machine, their parts, and modifications. As well as construction, structural design, working setup, functioning and machining tests are observed in this survey of Portable Milling Machine. Xie *et al.* (2014) developed a hybrid milling machine with actuation redundancy capable of five-face milling in one setup.

- CNC Grinding

Abrasive machining is one of the most critical finishing processes used in industries. Therefore continuous effort is going on these days to enhance the efficiency of this process by decreasing abrasive forces, increasing machining efficiency decreasing the temperature, improving shape accuracy and machined surface, etc., one such effort is the development of hybrid machining system for this process especially for grinding of special materials, alloys, composites, and ceramics. Ruszaj *et al.* (2017) presented the review various applications of hybrid grinding and electrochemical machining for sintered carbides, titanium alloys, nickel alloys and metal matrix based composites. It was worth to underline that recent developments in abrasive hybrid manufacturing processes also meet high industrial demands and challenges regarding geometrical precision and surface.

Sudiarso and Atkinson (2010) proposed the electrical dressing method for the dressing of grinding wheel to restore its cutting ability by developing a hybrid electrical dressing method for metal-bonded diamond grinding wheels which was a combination of electrochemical and electro-discharge dressing. Holtermann *et al.* (2014) presented the modeling and simulation of Internal traverse Grinding. Which is high performance grinding process incorporating a high rate of material removal combined with a high surface quality because of its unique grinding wheel geometry. Zhu *et al.* (2011) presented a hybrid process of grinding and

electrochemical refer [Fig. 19](#) for set up, removal for machining of small precision holes with hard-to-machine materials. The results revealed that precision holes with sharp edges and without burrs could be obtained while the material removals on grinding and electrochemical machining, were well balanced by rationally determining machining voltage, tool rotation speed and feed rate which is a practical, effective way to remove the recast layer ([Curtis *et al.*, 2009](#)).

Table 2 Vibration assisted hybrid manufacturing processes for different workpieces

Assisted hybrid manufacturing processes	Workpiece material	Outcomes
Vibration assisted		
Milling	H13 (Li and Wang, 2014), Al 6061 (Lian <i>et al.</i> , 2013; Ko <i>et al.</i> , 2011), Al6061-T6 (Chern and Chang, 2006)	Surface roughness heights reduced (Ko <i>et al.</i> , 2011), Reduction in tool life reported (Chern and Chang, 2006)
Grooving	Glass (Lee <i>et al.</i> , 2002), Al2024 (Koshimizu and Aoki, 2013; Ammouri and Hamade, 2012), Brass 28 (Kim and Loh, 2013), Pure nickel (Kim and Loh, 2011), Nickel alloy (Kim and Loh, 2011), Copper (Brocato, 2005; Brehl and Dow, 2007)	Micro-groove shapes are better (Gorczyca, 1987; Lee <i>et al.</i> , 2002) Chips average size get reduced (Koshimizu and Aoki, 2013)
Engraving	Al alloy (Koshimizu and Aoki, 2013), stainless steel (Koshimizu and Aoki, 2013)	Reduction in cutting forces observed (Koshimizu and Aoki, 2013)
Grinding	Ultra-fine grain cemented carbide (Onikura <i>et al.</i> , 2000)	Micro tools with smaller diameter and higher aspect ratio fabricated (Onikura <i>et al.</i> , 2000)
Drilling	Glass (Egashira <i>et al.</i> , 2002), AA2017 (Aziz <i>et al.</i> , 2012), SS41 (Chern and Lee, 2006)	Reduction in cutting forces upto 60%–70% reported (Egashira <i>et al.</i> , 2002)
Polishing	Binderless tungsten carbide (Suzuki <i>et al.</i> , 2006; Suzuki <i>et al.</i> , 2010; Chee <i>et al.</i> , 2011)	Achieved surface roughness in nm (Suzuki <i>et al.</i> , 2006; Suzuki <i>et al.</i> , 2010; Chee <i>et al.</i> , 2011)
Lapping	Silicon (Zhang <i>et al.</i> , 2006), Ti-6Al-4V (Wang <i>et al.</i> , 2002)	10 nm surface roughness achieved (Zhang <i>et al.</i> , 2006)
EDM	Stainless steel (Wang <i>et al.</i> , 2002; Yu <i>et al.</i> , 2009), copper (Gao and Liu, 2003), WC (Jahan <i>et al.</i> , 2010a; Jahan <i>et al.</i> , 2011; Jahan <i>et al.</i> , 2010b; Jahan <i>et al.</i> , 2012; Hung <i>et al.</i> , 2006), steel (Tong <i>et al.</i> , 2008), polycrystalline diamond (Mahardika <i>et al.</i> , 2012), brass (Endo <i>et al.</i> , 2008), nitinol (Huang <i>et al.</i> , 2003)	2/3 times increase of material removal rate (Mahardika <i>et al.</i> , 2012), increase machining efficiency by 60 times (Huang <i>et al.</i> , 2003)
WEDM	Ti-6Al-4V (Hsue <i>et al.</i> , 2012), tungsten carbide (Bhattacharyya <i>et al.</i> , 2007)	Machining efficiency increase 2.5 times (Hsue <i>et al.</i> , 2012)
ECM	Copper (Ruszaj <i>et al.</i> , 2003), tool steel (Ruszaj <i>et al.</i> , 2003), SUS304 (Ghoshal and Bhattacharyya, 2013)	Average surface roughness reduced upto 2.1 nm (Ghoshal and Bhattacharyya, 2013)

**Fig. 23** Mechanical strength vs. temperature. Reproduced from Sun, S., Brandt, M., Dargusch, M.S., 2010. Thermally enhanced machining of hard-to-machine materials – A review. *International Journal of Machine Tools and Manufacture* 50, 663–80.

Advanced Subtractive Technology

In case of advanced subtractive technology, manufacturing process energy supply is entirely different from conventional; however, the ultimate aim is to improve the material removal rate, surface finish, precision as well as effectiveness of the machining processes. In this case, the hybrid manufacturing processes existed can be classified as follows:

- Assisted Hybrid Processes
- Combined/Mixed Hybrid Processes

Table 3 Laser assisted hybrid manufacturing processes for different workpieces

Assisted hybrid manufacturing processes		Workpiece material	Outcomes
Laser assisted	Milling	H13 (Singh and Melkote, 2007; Singh <i>et al.</i> , 2008), Ti-6Al-4V (Ding <i>et al.</i> , 2012; Mohid <i>et al.</i> , 2014), A2 tool steel (Melkote <i>et al.</i> , 2009; Kumar and Melkote, 2012; Kumar <i>et al.</i> , 2012), Inconel 718 (Ding <i>et al.</i> , 2012), AISI D2 (Mohid <i>et al.</i> , 2014)	Mean thrust force reduction (Singh and Melkote, 2007; Singh <i>et al.</i> , 2008), increase material removal rate and reduction in resultant force (Ding <i>et al.</i> , 2012; Mohid <i>et al.</i> , 2014)
	Grinding	Al ₂ O ₃ (Chang <i>et al.</i> , 2012), Si ₃ N ₄ (Chang <i>et al.</i> , 2012)	Lower surface roughness is achieved (Chang <i>et al.</i> , 2012)
	Turning	Particulate reinforced MMC (Dandekar and Shin, 2013), Ti-6Al-4V (Dandekar <i>et al.</i> , 2010), steel parts (Ding and Shin, 2010), silicon (Mohammadi <i>et al.</i> , 2015)	Machining cost decreased by 30% (Dandekar <i>et al.</i> , 2010), improve in the machinability and good surface finish (Ding and Shin, 2010), surface roughness improved by 80% as compared conventional machining (Mohammadi <i>et al.</i> , 2015)
	Electrochemical machining	Stainless steel (Long <i>et al.</i> , 2015)	Improved machining rate and precision (Long <i>et al.</i> , 2015)
	Jet electrochemical machining	Al alloy, Ti alloy, Hastelloy and Stainless steel (De Silva <i>et al.</i> , 2004; Pajak <i>et al.</i> , 2006; De Silva <i>et al.</i> , 2011; Pajak <i>et al.</i> , 2004), Inconel 718 (Malik and Manna, 2017a; Malik and Manna, 2018a,b), EN-31 tool steel (Malik and Manna, 2019)	Increase in material removal rate, reduction in hole taper (De Silva <i>et al.</i> , 2004; Pajak <i>et al.</i> , 2006; De Silva <i>et al.</i> , 2011; Pajak <i>et al.</i> , 2004), reduction in taper, overcut, average spark affected zone (Malik and Manna, 2017a), reduction in surface height (Malik and Manna, 2018a), increase in material removal rate (Malik and Manna, 2018b)
	Electro discharge machining	2% Ni - 2% Cr case hardened steel (Li <i>et al.</i> , 2006), Ni-Ti based shape memory alloy (Al-Ahmari <i>et al.</i> , 2015)	70% reduction in drilling time with 42% cost reduction, improve production capacity by 90% (Li <i>et al.</i> , 2006), machining time reduced by 56%–65% without compromise hole quality (Al-Ahmari <i>et al.</i> , 2015)
	Water jet machining	Stainless steel sheets (Hock <i>et al.</i> , 2012), Brass sheets (Hock <i>et al.</i> , 2012), Polycrystalline CBN (Melaibari <i>et al.</i> , 2012),	Dross free cuts with small kerf width and reduced heat affected zone in water jet laser cutting (Hock <i>et al.</i> , 2012), increase cutting efficiency with improvement in surface quality (Melaibari <i>et al.</i> , 2012)

In case of *assisted hybrid manufacturing processes*, material is removed with the help of main/primarily machining process and the addition of secondary process is just to assist the primary machining process and improve the effectiveness of the machining. Secondary machining process may not directly engage in material removal. The assisted machining process increases the machinability of the material and enhances the performance of the main machining process.

Manufacturing process technology can be improved by combining two or more different machining action at the same time during workpiece machining. The combination of two or more manufacturing processes at the same time is known as *Combined hybrid manufacturing*. *Hybrid technology* is defined as the combining of at least two different sources of energy for production of different components (Mahdy, 2001).

Hybrid manufacturing is a promising technique, which is recently used in today's manufacturing industries for improving quality of machined parts for different superalloys and difficult to machine materials (Kozak *et al.*, 2004; Wang *et al.*, 2003; Kozak and Rajurkar, 2000; Yadava *et al.*, 2002; Rajurkar *et al.*, 1999; Nau *et al.*, 2011; Lauwers *et al.*, 2010, 2014). Rajurkar *et al.* (1999) described "*Combination of two or more machining processes for material removal*".

Assisted Hybrid Micro-Manufacturing Processes

In assisted hybrid micro-manufacturing there are basically two or more types of energy (such as thermal, mechanical, chemical or electrochemical etc.) is used to enhance the materials machining performance (Heisel *et al.*, 2011).

● Vibration Assisted Micro Manufacturing (VAMM)

In VAMM process vibrations of small amplitude applied to the tool, workpiece or work fluid during machining. Due to vibrations during cutting tool and chips loses contact on specified amplitude. This vibration assistance approach is applied to various conventional as well as non-conventional machining processes. In vibration-assisted micro cutting (VAMC) at a specified amplitude contact between the cutting tool and chips breaks resulting decrease in the machining forces and improves surface finish as well as tool life (Brehl and Dow, 2008). In VAMC surface cracks results due to tool hammering action (Lauwersa, 2011), in vibration-assisted EDM (Gao and Liu, 2003; Yu *et al.*, 2009; Sundaram *et al.*, 2008; Gama *et al.*, 2011; Jahan *et al.*, 2010a,b, 2011, 2012; Hung *et al.*, 2006; Tong *et al.*, 2008; Kim *et al.*, 2006b; Ichikawa and Natsu, 2012, 2013), in vibrations applied between the workpiece and the tool, which improves the flushing efficiency with increasing material removal rate and surface finish. Vibration also helps in removing of the debris

Fig. 24 Schematic of laser assisted milling (a), laser assisted grinding (b), laser assisted turning (c), laser assisted jet electrochemical machining (d), laser assisted electro discharge machining (e), and laser assisted water jet machining (f). Twin gas jet-assisted laser drilling through thermal barrier-coated nickel alloy substrates. *International Journal of Machine Tools and Manufacture* 49, 1126–1135.**Table 5** Combined hybrid micro manufacturing processes for different workpieces

Combined hybrid micro manufacturing processes	Workpiece material	Outcomes
Electrochemical Spark/discharge machining (ECSM/ECDM)	Glass (Wuthrich <i>et al.</i> , 2005; Wuthrich and Hof, 2006; Wuthrich <i>et al.</i> , 2006; Maillard <i>et al.</i> , 2007; West and Jadhav, 2007; Jalali <i>et al.</i> , 2009; Abou Ziki <i>et al.</i> , 2012; Abou Ziki and Wüthrich, 2013), steel (Coteață <i>et al.</i> , 2011), quartz (Yang <i>et al.</i> , 2010; Yang <i>et al.</i> , 2011; Kulkarni <i>et al.</i> , 2011), silicon nitride (Sundaram <i>et al.</i> , 2008), copper (Kulkarni <i>et al.</i> , 2011), pyrex glass (Kim <i>et al.</i> , 2006a; Zheng <i>et al.</i> , 2008; Cheng <i>et al.</i> , 2010), soda lime glass (Kulkarni <i>et al.</i> , 2011; Furutani and Maeda, 2008; Paul and Hiremath, 2014), borosilicate glass (Abou Ziki and Wüthrich, 2012), tantalum (Kulkarni <i>et al.</i> , 2011), alumina (Al_2O_3) (Abou Ziki and Wüthrich, 2012), stainless steel (Huang <i>et al.</i> , 2014), E-glass fibre epoxy composite (Manna and Narang, 2012)	Effectively used for the machining of nonconductive materials (Wuthrich <i>et al.</i> , 2005; Wuthrich and Hof, 2006; Wuthrich <i>et al.</i> , 2006; Maillard <i>et al.</i> , 2007; West and Jadhav, 2007; Jalali <i>et al.</i> , 2009; Abou Ziki <i>et al.</i> , 2012; Abou Ziki and Wüthrich, 2013, 2012; Yang <i>et al.</i> , 2010; Yang <i>et al.</i> , 2011; Kulkarni <i>et al.</i> , 2011; Kim <i>et al.</i> , 2006a; Zheng <i>et al.</i> , 2008; Cheng <i>et al.</i> , 2010; Furutani and Maeda, 2008; Paul and Hiremath, 2014; Manna and Narang, 2012)
Travelling wire electrochemical spark machining (WECSM)	E-glass fibre epoxy composite (Malik and Manna, 2016, 2017b; Manna and Malik, 2014), quartz (Kuo <i>et al.</i> , 2015; Rattan and Mulik, 2017), borosilicate glass (Bhuyan and Yadava, 2013, 2014), glass (Liu <i>et al.</i> , 2017)	Effectively machining of E-glass fibre epoxy composite in micron (Malik and Manna, 2016, 2017b; Manna and Malik, 2014), magnetic field introduction increased MRR with spark current reduction (Rattan and Mulik, 2017)

Fig. 26 Electrochemical Spark/discharge machining operation. Reproduced from Bhattacharyya, B., Doloi, BN., Sorkhel, SK., 1999. Experimental investigations into electrochemical discharge machining (ECDM) of non-conductive ceramic materials. *Journal of Materials Processing Technology* 95 (1–3), 145–154.

which results in lower thermal stresses, smaller heat affected zone and lesser surface cracks. **Figs. 20–22** shows schematic of some vibration assisted machining processes. **Table 2** shows the various vibration assisted machining processes.

- Laser Assisted Micro Manufacturing (LAMM)

High strength and heat resistant materials are often difficult to machine due to their physical and mechanical properties such as high strength and low thermal conductivity, which make the cutting forces and cutting temperature very high and lead to a short tool life. Because the flow stress and strain hardening rate of materials normally decrease with the increase of temperature due to thermal softening, thermal-assisted machining becomes a possibility when machining the hard-to-machine materials (refer **Fig. 23**) (Sun *et al.*, 2010). **Table 3** gives an overview of the performed studies on the laser-assisted micro-machining processes. The major work on laser-assisted micro-machining is to study some parameters such as surface roughness and micro-machining forces by manufacturing simple micro-grooves and then to compare with those obtained by conventional micro-machining. **Fig. 24(a–f)** shows schematic of some laser assisted micro-machining processes.

- Fluid Assisted Micro Manufacturing (FAMM)

This hybrid assisted micro-machining process includes applying water, gas, chemicals or special fluids on the workpiece with the aim of increasing the process performance. **Table 4** gives an overview of the micro-machining processes carried out with the assistance of various fluids. **Fig. 25** shows the schematic of the gas assisted laser micro drilling manufacturing process.

- Combined Hybrid Micro Manufacturing

In combined hybrid micro-machining, all the constituent micromachining processes simultaneously contribute to the material removal and affect the machining zone. Combined hybrid micromachining processes have giant potential to produce more complex parts with enhanced material removal rate, surface integrity and dimensional accuracy in a relatively short production time. Primary research in combined hybrid micro-machining field is on the application of electrical and electrochemical phenomena. Although combined hybrid micro-machining processes such as ECDM have been mostly used to fabricate 3D micro-shapes on nonconductive materials like glass and quartz, there is still a lack of such processes for manufacturing complicated 3D micro-structures. **Table 5** shows some work reported in the area of combined hybrid micro manufacturing.

Micro ECDM process involves a complex combination of the electrochemical (EC) reaction and electro discharge (ED) action. The electrochemical action helps the generation of the positively charged ionic gas bubbles, e.g., hydrogen (H₂). The electrical dis-

Table 6 Comparison between subtractive and hybrid machining processes

Type of machining	Machining process	Advantages and disadvantages	Applications/Type of cutting tool/Cost
Subtractive machining	Grinding	Advantages ● Investment is less ● Working principle and operation is simple ● It does not require additional skills ● Surface finishing will be approximate 10 times better as compared to milling and turning process of machining. ● Dimensional accuracy will be quite good ● Grinding process could be performed on hardened and unhardened workpiece Disadvantages ● Required tool is high cost ● Process is also a costly one ● It cannot remove the high amount of material; it only removes a little amount ● For removing the required amount from work it consumes more time	Applications ● Slitting & parting, ● Surface finishing, ● Deburring & descaling, ● Abrasive milling, ● Finishing cylindrical and flat surface, ● Grinding of various tools and cutters Type of cutting tool Multi-Point cutting tool Cost Installation cost is less but running cost is high
	Turning	Advantages ● All types of materials can be turned ● A most versatile machine capable of producing external and internal circular profile and flat surfaces ● Low tooling cost ● Large components can be turned Disadvantages ● Turning operation requires skilled operator ● Low production rate in turning machining operation ● Close tolerances and surface finish cannot be achieved	Applications ● Parting off ● Turbine parts ● Cylindrical shafts ● Gear wheel ● Bone and dental screw Type of cutting tool Single-Point cutting tool Cost Installation cost is high but running cost is lesser
	Milling	Advantages ● Variety of shapes including flats, slots and contours can be obtained through milling operation ● Versatile operation with a wide variety of tooling's and attachments ● Suitable for low and medium production rate ● Better dimensional control and surface finish Disadvantages ● Milling operation requires skilled operator ● Tooling relatively more expansion	Applications ● Surface contouring ● Slitting ● Gear cutting ● Straddle milling ● Key slots ● Grooves cutting ● Face and edge finishing Type of cutting tool Multi-Point cutting tool Cost Installation cost and running cost both are higher than grinding and turning
Hybrid machining	Laser assisted machining (LAM)	Advantages ● Increased machining rate ● Improved machining precision ● Machined any material irrespective of its hardness (i.e., conductive, non-conductive materials and polymers) ● Improve process productivity Disadvantages ● Microstructure of machined surface ● Presence of heat affected zone ● Thermal stresses developed ● Highly skilled operator is required	Applications ● Turbine blades parts ● Micro machining ● Die sinking ● MEMS fabrication ● Micro holes ● Surface texturing Cost Installation cost is more due to costlier laser assembly

(Continued)

Table 6 Continued

Type of machining	Machining process	Advantages and disadvantages	Applications/Type of cutting tool/Cost
	Vibration assisted machining (VAM)	Advantages ● Increased machining rate ● Improved machine precision ● Machined any material irrespective of its hardness ● Increased tool life, micro hole aspect ratio and micro cutting forces ● Increased flushing efficiency in fluid related machining ● Conductive, non-conductive materials and polymers Disadvantages ● Highly skilled operator is required	Applications ● Turbine blades ● Micro machining ● MEMS fabrication ● Micro and macro holes ● Surface texturing Cost Installation cost is less as compared to the LAM
	Fluid assisted machining (FAM)	Advantages ● Increased machining rate ● Improved machine precision ● Metals, polymers and ceramics ● Helps in flushing of reaction byproducts Disadvantages ● Less material removal rate as compared to conventional subtractive machining ● Handling of used fluid is also difficult ● Highly skilled operator is required	Applications ● Micro channels ● Micro machining ● MEMS fabrication ● Surface texturing and profiling Cost Installation cost is less as compared to the LAM and VAM
	Combined hybrid machining	Advantages ● Increased machining rate ● Improved machine precision ● Machined any material irrespective of its hardness ● Conductive, non-conductive materials, composites and polymers can be machined depends upon machine used ● Improved surface integrity Disadvantages ● Less material removal rate as compared to conventional subtractive machining ● Highly skilled operator is required ● Harmful gases generated during machining (i.e., ECDM, TWECSM)	Applications ● Micro holes/channels ● Micro machining ● Micro slits ● MEMS fabrication ● Surface contouring Cost Cost is lesser as compared to the LAM, VAM and FAM.

charge action takes place between the tool and the workpiece due to the breakdown of the insulating layer of the gas bubbles as the DC power voltage is applied between the tool (or cathode) and the anode, resulting in material removal due to melting, vaporization of the workpiece material and mechanical erosion. Gas bubble formation and sparking phenomena as in the ECDM process are exhibited as shown in Fig. 26.

Comparison Between Subtractive and Hybrid Machining

Table 6 shows comparison between subtractive and hybrid machining processes with their advantages, disadvantages, application and cost involved.

Summary

In the present book article various classes of widely used subtractive manufacturing technologies and their hybridizations have been reviewed. On the basis of the observations studies, following conclusions may be drawn:

- It has been found that the subtractive manufacturing class has undergone through various types of innovations that resulted into formation of better principle, procedures and also the machine tools.

- In comparison of manual systems, the CNC based subtractive technologies have produced great benefits not just in-terms of rapid production cycles but also to achieve better accuracies that led to the standardizations. Moreover, CNC based systems enabled the manufacturers with greater flexibilities to inculcate multiple operations all together and formed the concept of 'Hybrid Manufacturing'.
- In the recent decade, most of the research efforts have been made on the collaborations of the additive and subtractive manufacturing technologies which can deal with sophisticated engineering and other applications. Unfortunately, despite of the attempts made so far, no such technology has been commercialized as of today. The main reason behind may be the short outcomes of the research efforts or limited explorations of such innovations.
- Hybridizations of the non-conventional manufacturing technologies also played a great role in today's manufacturing sector, however, the output of such technologies usually lie on micro scale and are likely to be un-practical for mass production applications. Rather, the main role of such systems is economical and useful for small scale or job production runs.
- The future research efforts should be focused on the development of empirical and analytical relationships amongst the various process variables which can provide the practitioners a better control of the achievable characteristics.

Introduction

The World Summit on Sustainable Development (WSSD), or the ONG Earth Summit 2002, in Johannesburg, S. Africa, held under the aegis of United Nations, discussed the core issue of sustainable development faced by the world. WSSD proposed a key triplet term *people – planet – prosperity* to reflect the emerging view that sustainability requires a holistic balancing of economic, social, and environmental issues (White and Lee, 2009). Indeed, rising consciousness have brought in a much needed focus towards environment protection.

In general, the economic and environmental concerns have been perceived to be at odds with each other. However, lately, the issue of environmental consciousness, or “green management”, is being seen as intimately intertwined with the economic concerns. Indeed, Porter and van der Linde (1995) exhorted the businesses early on to end the stalemate between being green and competitive. Extant examples from practice, such as, Commonwealth Edison, Pepsi-Cola, Texas Instruments and Dow Corning, vouch for the economic benefits of the green practices (Wilkerson, 2005).

LMI Report (2003) mentions that organizations have witnessed an enhanced examination of not only the products flowing through various processes of a supply chain, but also the effects of these processes on environment and communities. The effort to reduce the impact of these activities on the environment has been labeled as green (or sustainable) supply chain management. As per this report, sustainable supply chain management approaches taken by various organizations can broadly be classified in two categories- external and internal. The external approach increasingly looks at the greening initiatives and their integration with the suppliers of the organization. The second approach involves an internal examination of how a firm designs, produces, and ships its products.

Green or sustainable supply chains, which are usually agile, adaptable, and aligned with both suppliers (on the upstream side) and customers (on the downstream side) provide companies with sustainable competitive advantages (Lee, 2004). Thus, it is imperative for organizations to measure the sustainability performance of their supply chains. The aspect of measurement is important since a common adage suggests that what gets measured gets improved. Measurement will thus help in improving and communicating the sustainability related performance of a supply chain. This is important in organizational goals and strategic priority setting. The measurement imperative has also become important in wake of recent environmental factors such as competition, globalization, uncertainty, regulation, public awareness, consumer rights and limited resources (Saeed and Kersten, 2017).

While the importance of the measurement indicators of sustainability practices in supply chain management cannot be emphasized enough, it appears that, due mainly to varied demand on the organizations to adhere to environmental standards, there is no common set of metrics for measuring sustainability performance of an organization, or its supply chains. Even when some metrics are reported in the literature, often there are inconsistencies or incompatibilities between various measures (Lehtinen and Ahola, 2010; Hassini *et al.*, 2012). Thus, the prime objective of this paper is to posit, based on the extant literature, a general set of sustainability indicators in supply chains. As discussed above, such a set of indicators would be helpful for future researchers as a reference framework to develop further studies in an area of important concern to supply chain managers and researchers.

The rest of this paper is organized as follows. The next section provides some basics of the supply chain of an organization, and the issues faced in its management. Section “Sustainable (or Green) Supply Chain Management” then specifically focuses on the sustainability (or greening) aspects of a supply chain. In Section “Sustainability Indicators in Supply Chains”, we develop the sustainability indicators of a supply chain. The next section provides a select group of case studies in the textile sector; a sector chosen to highlight the sustainability aspects of supply chain management. We conclude in the last section with implications for researchers, managers, and practitioners.

Supply Chain and its Management

As discussed extensively by Chopra and Meindl (2007), in its most general form, a supply chain can be defined as comprising of all of the entities involved in fulfilling a customer order. Specifically, we can visualize a supply chain as a system of organizations, people, activities, information, or resources involved in moving a product or service from supplier to customer. Thus, supply chain management involves activities that convert raw materials to finish goods to be delivered to a customer. In sustainable supply chain systems, several of these used products may re-enter the supply chain for recycling and reuse.

The above systemic view point of supply chain management is depicted in Fig. 1. As shown in the figure, the supply chain view emerges at the ‘input’ stage. The role of suppliers, availability of raw materials, natural resources, components, and managerial competencies is important at this stage. The second stage, that of ‘process’, involves the transformation of the input to saleable product or service. This stage involves the emphasis on manufacturing, production or services within the organization, often

Fig. 1 A systemic view of supply chain management.

involving the work-in-process. The third stage of 'output' focuses on the finished product as a result of the conversion process in Stage 2. This stage also lays emphasis on the customer related aspects like satisfaction, and consequently, linking it with the ultimate financial results of the company in terms of market share, revenues and profitability. From the above explanation of the first three stages, the following salient points emerge:

- (1) It is pertinent to note here that inherent in the factors at Stage 3 are the aspects of market demand, and distribution of the products (We will elaborate on the distribution aspects slightly later in this section).
- (2) This systems view of input-process-output has also appeared in the other management disciplines or discourses, and in particular, marketing. However, one indirect stage, which has specifically been included here, is that of feedback or recycling. This indirect stage has been shown by the dotted arrows in [Fig. 1](#).
- (3) The *feedback* aspect is important from the informational standpoint. Any information at the output stage (such as, about demand, customer satisfaction, or financial results) must be fed back to the input stage in order to take any corrective actions. This aspect takes care of the *control* aspect in the systemic view.
- (4) The *recycling* aspect in the indirect stage is more closely related to the sustainability of the supply chain of the organization. Thus, as depicted in [Fig. 1](#), after the product has been distributed and consumed, a responsible and sustainable organization needs to take care of the post-consumption treatment (or recycling) of the product, its packaging, and other related material. It is clear that the recycling aspect of the systemic view is closely related to the distribution view of a supply chain. This distribution view is presented below.

We now discuss the distributional aspect of a supply chain. This view is motivated from the marketing distribution channel (or value chain) of an organization and is presented in [Fig. 2](#). As shown in the figure, a typical supply chain comprises of several entities starting from the suppliers to the manufacturer, to wholesaler, to retailer, and eventually, for the end consumption by the consumer. Several pertinent points emerge from this conceptualisation:

- (1) While a single entity (such as supplier, or manufacturer) has been shown at each level, typically, there would be several entities at each horizontal level of a supply chain. Thus, the resultant supply chain structure that finally emerges is quite a complex one.
- (2) In a more complex structure, there may be a greater number of levels between the suppliers and end consumers. Thus, the role of information availability, or feedback, becomes quite crucial in longer supply chains. Due to stochasticity of demand, and information asymmetries, this problem may reveal itself in the form of bullwhip effect, which has been studied extensively in the extant literature ([Lee et al., 1997](#)). The downstream players, such as retailers, are closer to the end consumer and have faster and more accurate picture of demand.
- (3) In the distributional definition of a supply chain also, the importance of recycling is quite apparent. As can be seen from the figure, the post-consumption collection of the used product from the end consumer, and its recycling, have important ramification from the sustainability (or greening) standpoint of a supply chain. The recycling can be done at the level of both suppliers and manufacturers.
- (4) From [Fig. 2](#), it is clear that any greening initiative by a supply chain needs an integrated effort from the entire supply chain. Thus, the issue of channel power becomes quite important in this regard. Thus, if the manufacturer is a more powerful player in a supply chain, say, Procter and Gamble, then a number of greening initiatives may be initiated by the manufacturer from the upstream level. Alternatively, if the retailer is relatively more powerful player, say, Walmart, then the greening initiatives may be championed from the downstream level. It is clear from this explanation that suitable incentives (or contracts) should be in place for all the members of a supply chain to put in an integrated greening effort ([Swami and Shah, 2013](#)).

The conceptualisation of sustainable (or green) supply chain management is provided in the next section.

Fig. 2 A distributional view of supply chain management.

Sustainable (or Green) Supply Chain Management

In 2015, the United Nations adopted 17 sustainable development goals, with an aim to strive towards a sustainable world by the year 2030 (see “Relevant Websites section”). Some of these goals pertain to clean water and sanitation, affordable and clean energy and responsible production and consumption. Several countries adopted the UN agenda and agreed to strive to achieve these goals. While several of these goals are specific to responsibilities of governments and policy making bodies to design necessary regulatory frameworks and create ecosystems to help businesses and societies achieve sustainable development, much of the onus also lies with firms.

Several of these sustainable development goals provide directions for businesses to consider their impact on societies and environment besides just economic priorities. This three pronged approach means that firms can no longer continue to simply focus on economic objectives or profitability only, but also include environmental and social objectives in their strategic plans. Such an approach is also termed as the Triple Bottom Line Approach (see “Relevant Websites section”).

By its definition, the Triple Bottom Line approach tasks managers with a challenging yet achievable task of broadening firm’s objectives beyond profit making motive and includes aspects of environmental and social benefits. This is especially important in the context of supply chains, since growth of outsourcing over the last few decades has increased flow of raw materials, semi-finished and finished goods spread across geographical boundaries. A smartphone sold in a store in New York for example, may have been designed in Chicago, manufactured and assembled at Shenzhen and shipped via a third party logistics service provider in Hong Kong. Such product flows have led to increase in harmful impact of sourcing, production, transportation and packaging activities on environment and societies. Hence, the focus on environmental and social impact of firm operations and supply chains have assumed critical importance.

We now discuss the core concept of sustainability. The United Nations defines sustainable development as “*development that meets the needs of the present without compromising the ability of future generations to meet their own needs*.” (see “Relevant Websites section”) This means that firms may work towards economic goals, but should not exploit natural resources or societies to the extent of driving them extinct. Sustainability has thus, environmental and social dimensions. However, in this paper, we primarily discuss sustainability from an environmental (or greening) standpoint.

Environmentally friendly (or greening) initiatives of firms have received considerable attention from practitioners and researchers. Negative externalities related to firms’ operations and supply chains have led to increased focus on environmental impact of supply chains (For example, Bangladesh Factory fires (see “Relevant Websites section”) and Mattel toy recalls (see “Relevant Websites section”), to name a few). This has driven calls for closer integration of supply chains and environmental considerations. Such an integrated approach is referred to as Green Supply Chain Management (GrSCM). GrSCM is defined as “*integrating environmental thinking into supply chain management, including product design, material sourcing and selection, manufacturing processes, delivery of the final product to the consumers as well as end-of-life management of the product after its useful life*” (Srivastava, 2007).

Antecedents and Consequents of GrSCM

Analyzing this definition of GrSCM provides us with the following components of GrSCM activities, namely, green sourcing, green design, green manufacturing, green remanufacturing, reverse logistics and waste management. These components essentially form the antecedents of GrSCM construct.

On the consequences of GrSCM, several studies have shown that GrSCM activities lead to benefits for firms in the form of *price premium effect*, *cost reduction effect* or *demand expansion effect*. The consequences of the GrSCM construct can be further understood by revisiting the simple profit equation of a firm, which states that,

$$\text{Profit} = (\text{price} - \text{unit cost}) * \text{quantity sold} \quad (1)$$

Fig. 3 Green supply chain management framework.

The profit function is influenced by three parameters, namely, *price*, *unit cost* and *quantity sold*. It can be observed that *ceteris paribus*, an increase in price (or price premium) increases firm's profitability, decrease in unit cost (or cost reduction) increases firm's profitability and lastly, increase in quantity sold (or demand expansion) also increases firm's profitability. Thus, the relationship between economic performance of a firm and price, unit cost and quantity, give rise to consequences of GrSCM practices.

The price premium potential is realized when a consumer pays higher prices for the environmentally friendly product. Such an effect can arise out of higher willingness to pay for the green product or a positive image that a firm builds out of its environmentally friendly initiatives. The cost reduction effect is facilitated by reduction in wastage or efficient use of materials during conversion processes and is supported by remanufacturing and recycling efforts. The demand expansion effect is realized when market demand of the product increases as a result of greening activities of the firm (Ramani and Swami, 2017). In other words, with two manufacturers selling competing products, the consumer would be willing to purchase more of the product which is environmentally friendly. The above conceptualisation is summarized in Fig. 3 (For a detailed exposition, also refer Swami and Shah, 2009).

It can be thus, argued that economic consequences of greening initiatives of firms often lead managers to undertaken sustainability initiatives.

Environmental Taxation

A critical driver of GrSCM initiatives which may not be driven by economic consequences, but has the potential to significantly change the competitive landscape for firms is environmental taxation. While greening initiatives of firms can lead to economic consequences as illustrated through the previously discussed framework, governments and policy makers also play an important role in driving firms to adopt GrSCM initiatives. By using taxation as a tool, policy makers drive adoption of environmental initiatives in firms. For example, the Waste Electrical and Electronic Equipment Directives (WEEE) and Restriction on Hazardous Substances (RoHS) that came into effect in the European Union forced manufacturers to modify their products and supply chains (see "Relevant Websites section"). This also meant increased challenges in product design, setting up product collection centers, installing testing facilities, investing in testing equipment and personnel while also developing better products for longer lifecycles.

Environmental taxation can also lead to change in competitive strategy of firms (Ghosh *et al.*, 2018). For example, pollution norms or waste disposal norms enforced within an industry can create significant competitive advantage for firms which have already invested in zero emissions, zero waste disposal and recycling technologies. In contrast, laggards in the industry can stand to face penalty for inability to adhere to stricter pollution norms. Pollution intensive industries such as plastic manufacturing, textile and apparel manufacturing, paints and chemical manufacturing, among others, remain under constant scrutiny of governments globally. Similarly, stringent pollution norms in automotive industry have often forced manufacturers to invest in fuel efficient vehicles, hybrid technologies, fuel cells, electric vehicles and environmentally friendly vehicles. Firms like Toyota and Volvo for example, have increasingly improved their vehicle designs to make them more environmentally friendly (both internal manufacturing processes and external usage impact) (KPMG, 2016). Thus, it can be argued that in areas where voluntary initiatives or economic incentives of firms may not drive sustainability initiatives, policy makers often play an important role in driving green changes.

Given the various factors that drive sustainability initiatives in firms across different types of industries, a pertinent question that arises is what are the sustainability indicators that firms can adopt to measure sustainability performance? We discuss this in the following section.

Sustainability Indicators in Supply Chains

Given the requirements of measurement and dissemination of information on sustainability actions of firms, one of the key initiatives of firms have been the adoption of Global Reporting Initiatives (GRI) Guidelines. GRI is an international independent standards organization that has developed guidelines on sustainability reporting and helps companies report sustainability impact (see “Relevant Websites section”). The GRI standards developed by the organization cover any type of firm across sector, location and size. The standards continuously evolve and cover economic, environmental and social aspects. Some of the key factors that are considered under environmental and social aspects are provided in **Table 1**.

A closer look at **Table 1** provides an intuitive view of some of the key categories appear in each dimension. NASA, for example, provides evidence of the deteriorating air quality in parts of the world particularly in countries, such as, South Africa, Middle East, India and China (see “Relevant Websites section”). While much of this is attributed to the economic growth in these regions, policy makers in US, Europe and China have undertaken significant steps in designing provisions for air quality control. From India’s perspective, areas such as water and air quality continue to remain of primary concern for the economy. In this context, [Shah \(2017\)](#) analyzes the state of groundwater governance in India and suggests that greater coordination among various stakeholders is needed to improve groundwater sustainability in India. [Rehman and Hussain \(2017\)](#) discuss India’s solar energy requirements and propose a model of clean energy financial support to bridge the gap between solar energy requirements and development costs. These issues are also critical for businesses as their focus on energy and water requirements continue to grow.

The next key question is – what are the key sustainability indicators in which businesses focus on? [Aswani and Swami \(2017\)](#) have studied, in Indian context, the frequency of environmental phrases that occur in the sustainability reports of companies across Automotive, Conglomerate, Food and Beverage and Personal and Household sectors and report that firms have emphasized on issues related to emissions, pollution and climate change. The frequently recurring themes under each environmental category are highlighted in **Table 2**.

It can be observed that much of the sustainability reporting broadly covers key issues faced by firms. Sustainability reporting along the dimensions identified in **Table 2** have seen an increasing trend and more companies are adopting sustainability disclosures along with financial statements. While for many organizations sustainability reporting is still voluntary, in several countries, sustainability reporting has been made mandatory. For example, in India, Securities and Exchange Board of India (SEBI) has mandated top 100 listed entities to submit Business Responsibility Reports (see “Relevant Websites section”). In addition, the Companies Bill, 2011, in India has mandated firms to include Corporate Social Responsibility (CSR) policy in their reports (see “Relevant Websites section”).

Thus, the pertinent question arises on whether there are significant differences in sustainability indicators across sectors? [Kumar et al. \(2015\)](#) analyze the dimensions of sustainability reporting in the context of emerging economy such as India and conclude that there are no significant differences in sustainability reporting between different sectors as the majority of sustainability issues remain common to firms. However, [Aswani and Swami \(2017\)](#) find that the extent of disclosure may vary between firms. Interestingly, conglomerates with diversified businesses cover significant aspects of sustainability indicators compared to firms in a specific sector.

Table 1 Sustainability dimensions and key categories in each dimension (For a detailed exposition on the GRI standards, refer: <https://www.globalreporting.org/standards/gri-standards-download-center/>)

Sustainability dimensions	Category
Environmental	Materials, Water, Energy, Waste, Emissions, Biodiversity and Environmental Management Systems (EMS), Environmental Compliance
Social	Employment, Occupation Health and Safety, Labor/Management Relations, Training and Education, Diversity and Opportunity, Non-discrimination, Community Involvement, Customer Health and Safety

Table 2 Frequency of environmental phrases used

Category	Phrases
Water	Water, Groundwater, River, Marine, Lake, Abstraction
Energy	Renewable, Energy Efficiency, Energy Usage, Green Energy
Waste	Hazardous, Emissions, Recycle, Pollution, Toxic, Landfill, Incineration, Waste Discharge
Emissions	Climate Change, Greenhouse Gas, Carbon Dioxide
Biodiversity	Forest, Ecosystem, Ecology, Habitat, Greenfield, Land use, Wildlife, Brownfield
EMS	ISO 14001, Management systems, Environmental Audit

Note: Aswani, K., Swami, S., 2017. Analysis of sustainability reporting of Indian companies. In: Dhir, S., Sushil (Eds.), Proceedings of International Conference on Strategies in Volatile and Uncertain Environment for Emerging Markets, July 14–15, 2017, pp. 537–549. New Delhi: Indian Institute of Technology Delhi.

This leads to the next pertinent question on what sustainability actions have firms undertaken on measurement, and dissemination along key indicators? We discuss cases of few firms which have undertaken various initiatives in this area, in the following section.

Case Studies in Sustainability Initiatives

To understand the sustainability measurement initiatives better, we take a look at few global firms which are also often subject to the scrutiny of stakeholders for the environmental impact of their supply chains. Specifically we discuss the textile and fashion industry.

The consumption of textile in various forms is estimated at more than 30 million tons a year, which causes serious social and environmental impacts within a supply chain (Chen and Burns, 2006). The issues related to sustainability are critical in the textile industry, and its associated industries like the fashion industry. In order to reduce production costs, textile or apparel firms have been accused of traditionally taking benefit of low environmental awareness and lax regulatory systems in emerging economies. However, lately, some fashion companies, recognizing the importance of environmental imperatives, have tried to incorporate greening operations in their supply chains. Such firms include H&M, Zara, Patagonia, Levis, Uniqlo, The North Face, and so on. It is interesting to note that greater sensitization towards environmental perspectives has not only come through firms, but has also been demanded by their consumers. Indeed, the consumers' environmental attitudes have been found to directly influence their consumption pattern in the case of fashion products (Chan and Wong, 2012). There are also some evidences from prior literature that fashion consumers prefer green products and are even willing to pay higher prices for them (Shen *et al.*, 2014). The production process in this industry is highly intensive in its use of chemicals and water. Thus, the sustainability requirements are immensely important and are required to be followed under standards such as ISO 14000 (Li *et al.*, 2014).

We present some representative case studies of apparel fashion brands that have introduced the operational aspects of sustainability in their supply chains. The requirements of coordination and resultant conflict of being both green and profitable are apparent at each stage of supply chain, which includes production, distribution, marketing and retailing.

Zara

Zara is a chain of fashion stores owned by Inditex, one of the largest apparel manufacturer and retailer of Spain. It employs more than 170,000 persons. In 2017, the sales of Inditex were reported at 25.3 billion euros, having 7475 retail outlets, 450 million items a year, in more than 96 countries (Inditex Annual Report, 2017). With a fickle demand scenario that Zara faces, it has shown a rapid growth. Its business strategy is hinged on responsiveness and a relatively affordable price range. As compared to the average apparel industry design-to-sales cycle times exceeding six months, Zara has achieved it in five to six weeks.

Unlike the competitors which mostly manufacture in Asia, Zara uses a hybrid strategy of sourcing with flexibility and speed through European sources and low cost alternatives in Asia. About 60% of the manufacturing volume is outsourced by Inditex. The uncertain demand is met through European, and more predictable orders are serviced out of Asia. The responsiveness in meeting demand has been possible due to its initiatives like Green-to-Pack programme, which fills distribution trucks as densely and efficiently as possible, and using these trucks also in the reverse logistics to bring back returned items. The logistics centers of Zara have an EMS (environmental management system), which is ISO 14001 certified. Each Zara outlet sends a fixed number of orders per week (usually, two) on pre-specified days. Timings of trucks' arrival and leaving a store are fixed at specific times. The labeling and pricing of the garments are completed before arrival at a store, making them ready for sale. Because of the specificity of this well-designed system, every supply chain member, ranging from manufacturing, transportation to even customers, are aware of its timeline and the impact of various activities.

Some of the sustainable initiatives by Zara include the use of eco-friendly and sustainably sourced materials, such as, organic cotton. It also utilizes recycled materials, engages in upcycling, and creation of new fibers. Its procurement team also focuses on the waste reduction and reuse of the fabric material, under its Closing the Loop program. Zara uses special boxes and free collections services to collect clothing donations by the customers at both its stores and from homes. Still, a high-speed supply chain of Zara's requires constant attention if its members, managers and partners. The supply chain team of Zara continually observes the demand and keeps making adequate adjustments to the production plans.

H&M (Hennes and Mauritz)

Hennes and Mauritz (H&M), a leading fashion brand, was founded by Erling Persson in 1947 in Sweden. In 2017, it had more than 4500 stores in about 100 markets with more than 150,000 employees (H&M Group Sustainability Report, 2017). The analysis of its supply chain reflects a product design success story with several designers and pattern makers having a penchant for spotting latest fashion trends. The company's integrated logistics function supports cost-efficient supply. The bulk of its production is out of Asia, while a smaller proportion is in Europe. Distribution is the key aspect of its supply chain system with adequate supply controls and demand rationalizations. Through outsourcing and off-shoring, H&M maintains the agility and flexibility during the shifting trends.

Under sustainable operations practices, H&M has undertaken the objective, that, by 2020, it will use 100% sustainably sourced cotton; and, by 2030, it will use fully recycled or sustainable materials. It also aims at zero waste target to the landfills. H&M recycles cotton, polyester, polyamide, plastic, and wool material. It is certified by independent third party certification for categories, such as, organic fabric is certified by Global Organic Textile Standard (GOTS) and recycled ones are certified by Global Recycling Standard (GRS). From 2017, its Global Change Award annual innovation initiative would fulfill the objective of shifting to a circular fashion economy. Under this initiative, some of the awarded ideas include making vegan leather using grape waste from wine production, cow manure into textile fibers, and invention of digital threading.

Under its old garment collection program, it categorizes the collected garments as re-wears, re-usables, and recyclables into other fabrics. Recognizing that a large proportion of its carbon footprints is due to the transportation activity, H&M's has switched to more efficient and cleaner modes of transport, such as ferry and trains. It also makes sure that even the transportation boxes are reused. H&M follows the local environmental standards of the countries to which it ships the products.

The company also has an up-cycling program, which reprocesses the used textiles and fabrics to create upcycled and appreciated products. Customers are given additional discounts on the purchase of the upcycled products. Transparency is maintained in providing all information to the consumers through the website. Additional revenues accrued from such programmes are used for further funding of coupons, donations, and reinvestments in sustainability programmes. All of this results in an overall winning strategy from the perspectives of consumer, H&M, and environment.

Patagonia

Patagonia, is an American outdoor clothing company based in California that is in manufacturing and distribution of a wide variety of apparel and accessories for the outdoor lifestyles consumers. It has created quality products, which are sustainable and responsive to the environment. The company was formed in 1973 by an entrepreneur, Yvon Chouinard, who was himself quite enthusiastic about outdoor lifestyle. The mission statement of the company is to "build the best product, cause no unnecessary harm, use business to inspire and implement solutions to the environmental crisis" (O'Rourke and Strand, 2017).

Patagonia makes its business decisions on the basis of the assessment of environmental impacts every level of its production process. In 1996, it commenced its Common Threads Recycling Program, to switch to organic fibers despite having to incur some initial losses. Patagonia has a keen focus on technology and innovation. It invested a substantial amount of its reserves in R&D, including a new material testing laboratory. Some popular and patented sustainable fabrics developed by Patagonia include: Synchilla (recycled polyester fleece), Capilene (moisture-wicking polyester fabric), and a wetsuit lined with chlorine-free wool for increased insulation (see "Relevant Websites section").

Patagonia undertook significant strides in sustainability initiatives and launched a program called 'The Footprint Chronicles' to trace and track the flow of materials from sourcing to final goods stage. The objective of the program was to track the material flow for products of Patagonia. Out of several outcomes of this exercise, an important finding by the firm was the presence of harmful chemicals such as per fluoro-octanoic acid (PFOA) used in rain shell jackets which accumulated in the bloodstream of consumers with repetitive use. The finding was also covered by business press and non-governmental organizations (NGOs). The increased pressure from consumers, NGOs and media, coupled with the proactive sustainability initiatives of the firm, led it to work with its suppliers to find alternative sources of chemicals which would be environmentally and health friendly, while maintaining the quality of the final products of Patagonia. This was easier said than done. The change in design and sourcing material required costly investments by the company to stop the use of PFOA and design and develop alternative chemical sources for its rain shell jacket. Over a period of time Patagonia worked with its suppliers, to find alternative chemical substitutes, changed its solvent recovery system and developed a more eco-friendly version of the rain shell jacket (Ghosh and Shah, 2012).

Patagonia believes that better alternative sources of chemicals can be developed as substitutes and constantly innovates in the design and sourcing of material in collaborations with its suppliers. Patagonia has also decided to incorporate transparency in its supply chain and displays all its supplier activities, manufacturing processes and product flows to consumers. Patagonia has also come up with an interactive newsletter, Footprint Chronicles, to build customers' and stakeholders' awareness about its company's global operations. Since some customers might want to make decisions based on environmental or social issues, they are provided benchmark data on such parameters as a complete transparency effort. This initiative is further corroborated by the company's Reference Library, which provides extensive information on sustainable alternatives, say ranging from inventing bamboo fabric to having wool free of chlorine treatment. The decision to bring in a new partner into Patagonia's supply chain, known as "4-Fold," involves the assessment of its balance on four parameters: sourcing, quality, social and environmental (O'Rourke and Strand, 2017). Thus, Patagonia works consistently to make their supply chain more sustainable and socially responsible (see "Relevant Websites section").

Conclusion

Rising environmental consciousness has shifted much of the focus of business practice towards sustainability. In this paper, we underscore the strategic importance of supply chains and highlight factors that drive sustainability initiatives in them. With a particular focus on the Sustainable Development Goals of the United Nations, we discuss the evolution of Triple Bottom Line and Green Supply Chain management. We delve into the antecedents and consequences of green supply chain management and argue

that economic benefits can drive sustainability initiatives of firms. In this context, using the simple profit equation of a firm, we argue that green initiatives can lead to higher profitability, either through cost reduction, price premium or demand expansion effect. It is to be noted that these economic benefits are not mutually exclusive and can overlap each other. In other words, a firm can generate twin benefits of cost reduction and price premium effect through changes in its process and product design.

In several cases, where voluntary initiatives of firms may not suffice to bring in much needed change, policy makers and governments play an important role in implementing environmental taxation to drive green initiatives. Such policy changes can significantly alter the competitive landscape for firms and those who have proactively engaged in adopting environmental initiatives may stand to benefit vis-à-vis their competitors.

We also discuss various sustainability indicators that firms can adopt in reporting their initiatives. In this regard, with a particular focus on environmental reporting, we look at some key dimensions along which measurement and further information dissemination can be done. Finally, we look at various initiatives undertaken by firms globally to incorporate environmental changes in their products and processes.

The lessons drawn in this paper have wide applicability across industry sectors. While we have attempted to closely integrate supply chains and environmental consciousness in our discussion, much needs to be in done in practice to stem the harmful effects emanating out of supply chain activities. There is an urgent need to align supply chain activities in line with Sustainable Development Goals for environmental protection.

Much of the issues discussed here have implications for researchers. While anecdotal evidence supports the conceptual green supply chain framework presented in this paper, scope for empirically validating the framework remains. Further, researchers can also look to analytically validate the model by incorporating cost reduction and price premium effects, or cost reduction and demand expansion effects. Analytical models incorporating uncertainty of green demand could also be built.

While the paper highlights various sustainability indicators adapted by firms, the metrics evolve on a periodic basis. Both practice and research have much to contribute here, since the development of sustainability metrics could be done with close tie up between academia and industry. The applications of improved sustainability metrics would further assist effective sustainability reporting.

Introduction

Environmental concerns have grown exponentially owing to the increasing consumption of natural resources and pollution. Therefore, to address the aforementioned concerns it becomes important to successfully implement the sustainable manufacturing systems. A number of definitions have been proposed to define the word sustainability. For instance sustainability has been defined by former Prime Minister of Norway Gro Harlem Brundtland as the framework wherein the needs of the present generation are met without compromising the ability of future generations in meeting their requirements (Jawahir, 2008). In accordance with Jawahir and Wanigarathne, sustainability meets the requirements of the customer base with simultaneous management of available resources (Jaafar *et al.*, 2007; Rosen and Nazzal, 2013). They opined on the three pillars that define the term *sustainability*: Social directions, economic factors, and environmental concerns.

Specific objectives are associated with each of these sustainability aspects. These specific objectives are to be met to ensure the development and implementation of sustainable environment. Ethics, quality of life, safety, and improvement in health are the major objectives related to the social aspect of sustainability. New business opportunities, new job roles and employment, and process and product development are the major objectives associated with the economic aspects of sustainability. The environmental aspect of sustainability is met with implementation of regulations on clean water, air, and soil (Epstein, 2018).

The three main levels that aid in identification and analyzing the conceptual framework of sustainability are system, process, and product levels. Required sustainability goals can be achieved through effective interactions amongst the aforementioned levels. The perception of product level focuses on recycling, remanufacturing, recovering, reusing, reducing, and redesign. The process level focuses on reduction of toxic waste, hazards, and energy consumption. This is achieved through the employability of optimized processes, which in turn is reflected in an effective methodology related to process planning. An efficient supply chain reflects the system level perception of sustainable manufacturing. The supply chain will be sustainable if it considers all the stages related to the life-cycle of a product, that is, premanufacturing phase followed with manufacturing stage and ultimately the usage phase and postusage stage (Badurdeen *et al.*, 2009). In totality, the following are the major objectives of a sustainable manufacturing framework: Reduction in consumption of energy, waste reduction, improvement in durability of the product, elimination of toxic waste, removal of health hazards, enhanced remanufacturing, reuse, and recycling.

Owing to the importance of sustainability, the present article is a genuine effort to review the approach of sustainable manufacturing through analysis of assessment methods, techniques, and tools for implementation and the related concepts. As such the article begins with a discussion on elements of sustainable manufacturing, which is followed with the associated needs and concepts. Design for sustainable manufacturing systems is elaborated in the subsequent section. The article then goes on to discuss the effective implementation of sustainable manufacturing framework followed by elaboration on assessment of approaches for sustainable manufacturing. Future trends in the domain of sustainable manufacturing have been highlighted towards the end of the article, which terminates with the concluding remarks.

Key Elements Related to Sustainable Manufacturing

Evolution of sustainable manufacturing has taken place through several paradigm shifts of manufacturing, that is, traditional, lean, green, and sustainable (Hartini and Ciptomulyono, 2015). The existing 3R approach has been modified to 6R by the addition of three more dimensions related to sustainability: Remanufacture, redesign, and recover. Postuse activities are carried out to collect the end-of-life products and therefore serve the objective for the recover phase. Simplification of postuse processes serves to achieve the challenges associated with environmental concerns and hence the redesign element of the 6R approach. The remanufacture element aids in enhancing the product performance by concentrating on savings of cost, energy, resources, and produced waste. Information on implementation of sustainable manufacturing framework is one of the critical aspects in development and enhancement of sustainable business models. The successful implementation of a sustainable business framework involves three major phases (Hamalainen *et al.*, 2018): Research, development, and commercialization. In the research phase, the specific requirements related to sustainability are examined, evaluated, and developed. This may include the impacts of climate change, various causes of pollution, and utilization of easily available and abundant renewable resources. The main goal of this phase of implementation is to ensure that sustainability is established and maintained at the precompetitive level and therefore has a very high potential in successful implementation of a sustainable manufacturing environment. The research phase concentrates on the major environmental issues related to manufacturing. In the second phase of implementation, that is, the development phase, various tools and methods (Mota *et al.*, 2015; Nazzal *et al.*, 2013) are employed to enhance environmental performance. Design for environment, life cycle analysis, and assessment of environmental footprint are some key indicators for environmental

performance. The last phase of implementation is the commercialization phase, which aids in refining the previous phases. Effective cooperation is established between the suppliers, vendors, and the customers.

Needs Related to Sustainable Manufacturing

Another important aspect that plays a critical role in achieving a sustainable manufacturing system is the comprehension of needs in defining the path to adoption of sustainable manufacturing (Cherrafi *et al.*, 2016). According to the literature, there are three important elements that define and describe completely the requirements of sustainable manufacturing: Information, management and culture, and procedures. Effective assessment can be made by providing the required qualitative and quantitative information. Specialized departments oriented to sustainability have to be built inside an organization to promote the development of sustainability culture. Procedures must be in place to ensure the application of the strategies and the objectives for a sustainable organization.

However, to enhance the performance pertaining to sustainable manufacturing, a number of needs are desired including concepts, data, government policies, integration, research, manufacturing practices and methods, and tools. The comprehensive examination of environmental, social, and economic aspects as well as other considerations is one of the additional needs for the improvement of sustainability performance. These concepts of sustainability are supported through development and continual enhancement of the developed method and tools. Requirement of comprehensive and robust data aids in analysis of environmental impact as well as related sustainability assessments. Data is however required across the various phases of the product life cycle. Sustainability indicators are required to monitor the effectiveness of practices in place to ultimately result in increasing awareness of sustainability amongst the customers and suppliers. Government policies on sustainability programs are required to ensure cooperation between the companies and the government itself. The policies are created considering the environmental impact. For continuous improvement in sustainable systems, industrial and academic research is indeed required that focuses on design and manufacturing in the backdrop of environmental considerations. Integration of the aforementioned needs representing the sustainability requirements on societal, economic, and environmental aspects is a very important requirement of enhancing the performance of sustainable manufacturing.

Sustainable Manufacturing and Design Approaches

To achieve the desired target for design for sustainability systems, several objectives are to be met. These objectives are designing for effectiveness of cost, optimal usage of material, efficiency of energy, disassembly of products, recycling, repair and reuse of products, remanufacturing, and continuous improvements (Jovane *et al.*, 2008).

The concept of “design for sustainability” is often considered as unique loop encompassing integration between substance and information loops (Jovane *et al.*, 2008). Design for remanufacturing, recyclability, manufacturability, social impact, resource utilization, environmental impact, and economy forms the major pillars for sustainable manufacturing environment when looked at from the perspective of process and product levels. The main objectives in accomplishing design related to environmental impact are efficiency, cobalance, and effects of environmental factors (Bhamra and Lofthouse, 2016). On the other hand, renewable sources of energy, operational costs, utilization of material resources, consumption of power, and energy efficiency results into achieving design for utilization of resources and economy (El-Halwagi, 2017). Design related to manufacturability considers development of newer techniques for storage, enhancing methods of manufacturing, establishment of newer methods for transportation, and assembly of products and packaging (Anderson, 2014). Different aspects such as product reliability, effectiveness of product function, ergonomics, ease of product use, and durability are the key elements for achieving design for functionality (Badurdeen *et al.*, 2013; Arnette *et al.*, 2014). Design pertaining to social impact considers ethical responsibility, health-wellness effect, and operational safety (Bennett *et al.*, 2017; Sutherland *et al.*, 2016). Smart techniques and hence development of advanced methods for recycling and remanufacturing are accounted in design for remanufacturability and recyclability (Veelaert *et al.*, 2017; Prendeville and Bocken, 2017). This aids in enhancing the efficiency of energy and material usage.

Implementation of Effective Sustainable Manufacturing Systems

Effective implementation of sustainable manufacturing systems can be ensured once the needs, elements, and the models associated with sustainable manufacturing have been defined. On achieving the aforementioned objectives, implementation of a sustainable manufacturing environment can take place with suitable understanding of the different implementation methodologies. The present section of the article discusses different practices and recommendations for effective implementation of sustainable manufacturing systems. The major requirement relating to the practical aspects of system, product, and process levels needs to be fulfilled to achieve sustainable manufacturing systems. A few of the related aspects are (Chen *et al.*, 2014) applications of principles related to utilized materials that are recyclable and nonhazardous and hence the related inputs; employability of efficient systems for logistics and transportation; development and planning of manufacturing processes that consumes less power,

water, and materials; development and application of design concepts that promote the usage of fewer resources; and development of product design concepts resulting in recyclability, remanufacturability, and reusability.

There are number of implementation stages that require their major objectives to be fulfilled so that the overall objective of the sustainable manufacturing approach is achieved. The various steps in implementation are development of work practices and maintenance strategies, optimization of process, substitution of raw materials, new technologies, and lastly the design of new product (Fargani *et al.*, 2017; Rodrigues *et al.*, 2016; Engert and Baumgartner, 2016). A brief discussion on each implementation steps follows next.

Development of work practices and strategies of maintenance: This implementation step of sustainable manufacturing system is often referred to as the housekeeping step. Production operations are made effective through the monitoring mechanisms, management, and scheduling of inventory. Effectiveness can be measured in terms of sustainable training programs, maintenance of equipment, and reduction of losses from leaks.

New product design: This step of implementation of sustainable manufacturing systems is often considered as the most difficult step. This step involves the transfer of the entire system of an organization from a zero sustainable environment to a full and well-established sustainable one.

Substitution for raw material: One of the major steps in achieving a sustainable manufacturing environment is to replace the hazardous chemicals and materials with the sustainable materials that have less adverse effect on the environment and health. Therefore, the major objective of this step is the reduction of concerns related to health and the environment. Furthermore, the goal of reduction in regulatory costs pertaining to storage and disposal of materials is also met through this step.

Optimization of different processes: This step involves the development of manufacturing processes such that waste materials can be reused, raw materials can be conserved, and waste is minimized. This can be achieved for instance by determination of optimal settings for each operation, changing of certain steps in specific manufacturing processes, and relocation of the machines so that the total movement of the machines can be minimized. Energy-efficient technologies that offer a supporting framework for sustainable manufacturing environment are another step to successful implementation of sustainable manufacturing systems. Energy efficiency can be achieved through the use of minimum lubrication, promoting dry cutting (Kaynak *et al.*, 2013), artificial intelligence methods (Renzi *et al.*, 2014), waste management principles (Kerry, 1988), and cryogenic approach (Wang and Rajurkar, 2000).

Newer methodologies and technologies: The step depends on the employability of energy systems with relatively higher efficiency. Energy efficient systems will ultimately aid in enhancing the environmental impact and the associated performance levels. The energy efficient methods have the potential ability to save heat and energy. However, a huge capital investment is required for effectively keeping such systems in place to achieve the desired sustainability effect.

Previous studies have revealed many successful attempts for implementation of sustainable manufacturing systems. Furthermore, attempts have also been made to link between manufacturing needs and the aspects related to sustainability such as management of waste, consumption of energy, and health and environmental concerns (Pereira *et al.*, 2017a,b; Polvorosa *et al.*, 2017; Hegab *et al.*, 2018a,c,d; Hegab and Kishawy, 2018; Eltaggaz *et al.*, 2018a,b).

Assessment For Sustainable Manufacturing Models

Once the sustainable manufacturing models have been implemented, it is also required to put in place an effective assessment model to evaluate the performance of sustainability systems. Personal health and safety, consumption of energy by various processes, management of the generated waste, environmental impact, and manufacturing costs are the five major elements that aid in assessing the sustainable manufacturing environment (Álvarez *et al.*, 2016; Chang *et al.*, 2017; Hegab *et al.*, 2018e). Subclusters and individual metrics related to each of the elements have (Kishawy *et al.*, 2018) been depicted in Figs. 1–5 respectively. Numerical and analytical models can be established for modeling of waste management, manufacturing cost, and

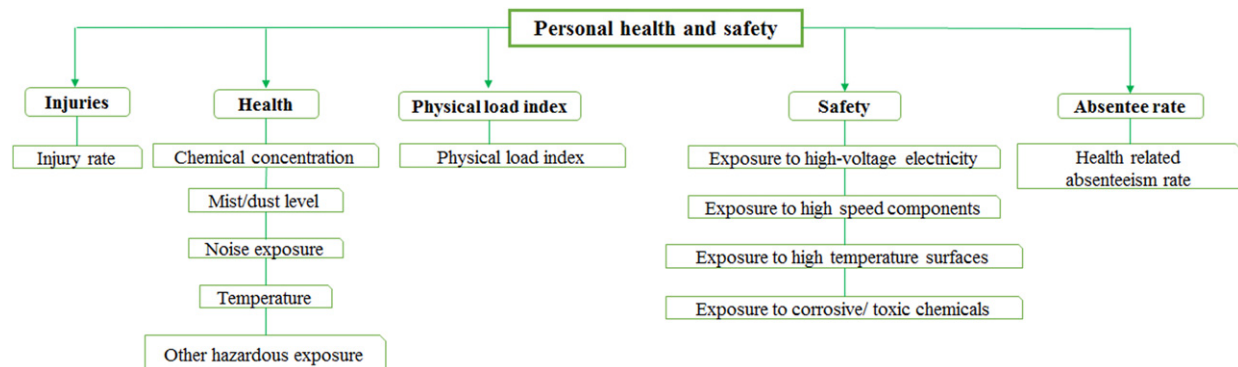

Fig. 1 Subclusters and individual indicators metrics for personal health and safety.

Fig. 2 Subclusters and individual indicators metrics for energy consumption.

Fig. 3 Subclusters and individual indicators metrics for waste consumption.

Fig. 4 Subclusters and individual indicators metrics for environmental impact.

energy consumption (Bertoni, 2017; Nee, 2015). However, the experience of the designer and their judgment can be used to express other key elements, that is, impact of environment and personal health and safety (Liu *et al.*, 2008). The assessment model must be able to effectively integrate and analyze the effects of all five major elements simultaneously.

Fig. 5 Subclusters and individual indicators metrics for manufacturing cost.

Another perspective from the product point of view can be expressed in terms of three main elements, that is, social, environmental, and economic aspects (Zhang and Haapala, 2015). The social impact aspect includes the following subclusters: Regulations related to social impact, human rights implementation, characteristics and benefits to employees, and health and safety impacts. Waste and emissions, end of life product, efficiency of material utilization, and energy usage are the subclusters related to the environmental aspect. As far as the economic aspect is concerned, the major subclusters are financial losses, economic growth benefits, indirect costs, direct costs, and initial investments.

A number of advantages are associated with the application of sustainable manufacturing models. As for instance, reduction in energy consumption, reduced waste, enhanced durability of product, enhanced performance of the systems, and better conditions for health and safety.

Conclusion

The present article has presented a discussion on sustainable manufacturing approach. This has been presented in the context of design, concepts, and techniques of implementation, and methods of assessments. The required target of sustainability has been achieved through the interaction amongst various levels, that is, system, product, and process. The following key subobjectives were identified in achieving the overall objective of sustainable manufacturing environment: Motivation towards usage of renewable energy resources, enhanced quality of life, enhanced quality of product, reduction in environmental impact, elimination of the health hazards, and improvement in durability of product, reduction in wastage of material, and reduction in consumption of energy. Several needs were identified to achieve the aforementioned subobjectives. These are integration, research, data, methods, and approach. Several aspects related to design that play an instrumental role in implementation of sustainable manufacturing environment are design for social impact, design for functionality, design for manufacturability, design for utilization of resources and economy, and design for environmental impact. Different stages key to the implementation of implementation of sustainability systems as identified from the literature surveyed were development of improved work practices, optimization of manufacturing and the associated processes, substitution of hazardous raw materials, employment of newer technologies, and development of newer designs of product. Solid assessment models and their need after the implementation phase have also been highlighted. It can be concluded that an effective sustainable manufacturing environment and its periodic analysis through different assessment models can aid in providing optimal performance levels.

Although there is a greater focus on the sustainable environment in the scenario where there is a greater concern towards the environment, the concepts and the related definitions are still inconsistent with the scientific community. There are wide variety of performance measures and instruments for judging sustainability. However, this presents another complexity to define completely the effective implementation of a sustainable environment. Thus definitions and proper understanding of the concepts of sustainability are one of the key barriers for its acceptance amongst the industries.

Manufacturing units need to evolve through the associated complexities and implement the various elements of sustainable manufacturing effectively so as to counter the growing concern towards the environment and hence human health.

Future Scope of Research

The present article has outlined the crucial understanding on the needs, techniques of implementation, and methods of assessments in accomplishing a sustainable manufacturing environment. Furthermore, the three major phases to achieve and hence successfully implement the expectations of manufacturing systems with sustainability characteristic features, that is, research, development, and commercialization, have also been highlighted in the present context. The major research gap lies in the

identification of effective implementation techniques and the desired needs. Therefore, a lacuna still exists for a detailed guidelines that can ultimately aid in defining the related conceptual framework and sustainable manufacturing practice techniques. Furthermore, artificial intelligence based models need to be promoted to achieve the goals of sustainable manufacturing. Also it is required to develop and enhance the current technologies relating to sustainability so that more benefits can be achieved through the employability of a sustainable environment.

Sustainable Production and Consumption – Business Perspective

Vivek Roy, Goa Institute of Management, Sanquelim, India

Introduction

The contemporary business environment witnesses a heightened concern toward sustainable development. Sustainable development seeks to surpass the standalone pursuit of economic progress, and advocates a further consideration to the environmental and social goals in business decisions. Sustainable development now stands as an agenda of international prominence, and the paradigm of sustainable production and consumption (SPaC) forms a key goal of the 'United Nations Development Programme' to transform modern-day nations, society, and businesses in the frame of sustainability. SPaC thus represents an ambitious response to the targets of sustainable development through its integrated consideration toward production-consumption systems in the modern economy. This response specifically aims to achieve the production and consumption of products, services, and resources through innovative ways that are environmentally benign, economically viable, and socially beneficial. The realization of SPaC depends on the active contribution of various stakeholders such as government, business, communities, households, and other non-business actors.

The Rationale of Sustainable Production and Consumption

Response to sustainable development concerns prevailing in the business environment has traditionally been either production- or consumption-orientation. While the production-oriented response lays an overarching focus on regulating the production systems to yield sustainable products and services, the consumption-oriented response is a standalone focus to generate awareness among the consumers to consume responsibly. It is however the 'rebound effect' that underscores the fundamental shortcoming inherent in these standalone approaches by accounting the logical offsetting of sustainability leads generated within one front (either production or consumption) by uncontrolled advancements over the other. For example, energy-efficient products may lead to a rise in household consumption due to cheaper operating costs. Overcoming this limitation is highly dependent on an integrated consideration to production-consumption systems. SPaC is therefore a more proactive response to the sustainable development agenda, which advocates the amalgamation of production and consumption perspectives to reveal a clearer picture of challenges and solutions by focusing on the complex inter-relationships between the two fronts (Roy and Singh, 2017). Fig. 1 presents the conceptual representation of SPaC.

SPaC is thus an advanced perspective to govern the effectiveness of public policies and business models for a sustainable business environment. This can be better achieved through diverse interpretations which the view of amalgamation (Fig. 1) inherent in SPaC facilitates.

The first key interpretation of SPaC lies in a production-dominant logic that addresses the question 'how production systems can foster sustainable consumption?'. This logic of SPaC outlines explicit enabling mechanisms that can facilitate the development of sustainable products and services to promote responsible consumption patterns. The typical guiding philosophies comprise of (a) produce through responsible consumption of resources, (b) produce through responsible disposal/treatment of wastes and pollution prevention, (c) design for sustainability, (d) consumer involvement in product design, (e) product service/repair,

Fig. 1 The region of sustainable production and consumption (SPaC). Adapted from Roy, V., Singh, S., 2017. Mapping the business focus in sustainable production and consumption literature: Review and research framework. *Journal of Cleaner Production* 150, 224–236. doi:10.1016/j.jclepro.2017.03.040.

(f) certification and product labeling to inform consumers about sustainable product/service offering, (g) fair trade – assurance of minimum price and benefits to producers at the bottom of pyramid, (h) ethical marketing – marketing approaches that do not promote overconsumption, (i) production-based responsible consumption – producer's role in educating consumers on sustainable consumption patterns and sustainable products, (j) using less – producer's role in facilitating reduction in the rate of consumption, (k) increase wisely – facilitating coordinated increase in the consumption of under-consumers, and (l) responsible procurement (Lebel and Lorek, 2008).

The second key interpretation of SPaC propagates a consumption-dominant logic which outlines the key role of consumers in affecting the production decisions of firms. For example, consumers may prefer to not consume a product or service that was produced unsustainably. This logic explains the critical role of consumers in pressurizing firms to facilitate (a) choices with sustainable product portfolios, (b) responsible and fairly priced consumption options, (c) replacing products with services, (d) greater accessibility to sustainable and resource-efficient products, (e) products that are easy to repair, (f) products that are innovative and multi-functional, (g) sharing of products, and (h) recycling and take-back policies based on extended producer responsibility (Haake and Jolivet, 2001).

These logics are complementary to each other in strengthening the position of SPaC in the contemporary business environment. They characterize the extension of responsibility for both producers and consumers to systematically involve each other in decision making. The interaction of these logics is however required to be interpreted through the contextual lens of economic development based on the developed and developing economies. First, it is critical for developing economies to facilitate SPaC in a manner that does not curtail economic welfare. Realizing this aspect forms the key challenge in the progress of SPaC. The current state of knowledge suggests that the radical goal of SPaC needs to be attained through the appropriation of achievable targets. For example, it can be feasible for a developing economy to embark on the transition toward SPaC – by jointly working on boosting the environmental and social quality of local production, and on fostering the preliminary awareness regarding sustainable consumption patterns. Second, given the advent of globalization, it is also important to focus on the responsibility of developed economies in leading the SPaC initiative on a global scale. For example, how can a firm situated in the developed economy can support its outsourcing business partners in the less developed nations to achieve SPaC.

The innate distinction in these economic contexts suggests that SPaC can primarily initiate from a policy focus to develop tailor-made pathways to sustainable development. The policy focus outlines the intervening role of government in supporting the multiple layers of the economy such as global trade, national market, and everyday life in regards to SPaC. The typical policy responses can be based on the principles of efficiency, sufficiency, and deliberation. The approach of efficiency focuses on boosting the technological competence of infrastructures to generate sustainable products and services with lesser resources and pollution. The sufficiency framework relies on regulating overconsumption by prompting the consumers to carefully evaluate their purchase decisions in the frame of sustainable integrity. The approach of deliberation develops information sharing and awareness generating mechanisms to achieve an overall consensus among the producers and consumers to achieve SPaC. These approaches are however constrained by the key responsibility of the government to mitigate the chances of market failures that may result from the interaction between sustainability principles and traditional profit-maximizing protocols prevailing in the business environment.

Apart from the government's role in defining policies, SPaC can also initiate from the secondary position of voluntary commitment by corporates to shift to innovative business models based on SPaC principles. Corporates may alternatively respond to the stakeholder pressures from governments (national and international), local communities, activist groups (such as NGOs), business partners, shareholders, and employees. Stakeholder pressures typically account a firm responsible for the social and environmental externalities generated from its economic activities. Ignoring such pressures may attract lawsuits, penalties, legal actions, public relations expenses, litigation fees, reputational damage, and the loss of consumer/employee confidence. Apart from the view of pressures, firms can recognize the potential competitive advantage and incentives inherent in SPaC based business. As such, SPaC compliance facilitates the firm with access to newer business opportunities in the globalized economy that specify sustainability as the precondition to supply.

The tertiary position regarding the initiation of SPaC in the business environment may involve an advanced state of collaborative action between governments, corporates, and other stakeholders to assign concrete roles and responsibilities. Such a state can profoundly govern the formalization of sustainable development agenda in the business environment toward the creation of a circular economy. It is however important to note that this progressive state of SPaC implementation is highly dependent on the achievement of significant advances along the primary and secondary fronts of SPaC initiation.

Based on these fronts, important characteristics can be derived to inform the contexts of developed and developing economies. The developed economies are more advanced in propagating SPaC through policy frameworks and voluntary involvement of corporates. Countries for example Finland, Germany, and United Kingdom have even moved to the advanced stages of SPaC by developing integrated systems that link production and consumption (Berg and Hukkinen, 2011; Lehtoranta *et al.*, 2011). The developing economies however witness preliminary efforts of the corporates to embrace SPaC, and government policies in these countries largely remain oriented toward economic development. The developing countries in the advanced stages of economic growth such as emerging economies (India, China, Brazil, Russia, South Africa, etc.) have started to face stakeholder pressures demanding stringent regulations on SPaC through dedicated policy frameworks. Such nations have resultantly started to consider the trade-off between economic development and sustainability, and have embarked on pilots to model policy frameworks targeting SPaC. For example, emerging economies such as China, India, and Turkey have developed government replacement and

subsidy policies in various industries to promote remanufacturing and generation of demand for remanufactured products (Wang *et al.*, 2019).

SPaC thus represents the facilitation of radical shift in the business environment to move away from the usual business outset of profit maximization. Implementation of SPaC is heavily dependent on the development of concrete agendas that guide the noted fronts. This requires accessing the strategic and operational issues embedded in the pathway of SPaC implementation to gauge the real picture of challenges and potential solutions.

The Strategic and Operational Issues in the Implementation of SPaC

The Strategic Issues

The achievement of transformation toward SPaC in businesses can be characterized as a complex journey which involves a multitude of stakeholders including the government, corporates, and consumers. The complexity emerges from the outset of the journey toward sustainable development which intends to propagate itself in the premise of established protocols of economic development. The journey therefore witnesses a natural resistance from the stakeholders involved in terms of their willingness to embrace radical shifts. Thus, the fundamental aspect concerns with facilitating a buy-in among stakeholders toward sustainable development at the systems level. The key strategic issues in this regard are segregated in the following.

Mainstreaming

Mainstreaming is the initial strategic response in this regard, where the key focuses lie in raising the awareness of stakeholders regarding sustainable development, and advocating the need to embrace SPaC in traditional production-consumption systems by locating the entry points. This can be achieved by systematically integrating the SPaC concern into existing programs and policies through gradual phases of developments (Cohen, 2010).

The first phase of mainstreaming involves the mapping of government, political, and socio-economic conditions to locate the contextual forces that would influence the course of transformation toward SPaC. The typical aspects to focus on targeted consultations with stakeholders may include (a) mapping the perspectives of diverse agents such as industry bodies (industry associations, chamber of commerce), business (owners, proprietors), NGO, governments (provincial and federal), civil society, media, academics and research institutions, consumer lobby groups, and retailers – in shaping the production and consumption trends, (b) locating key individuals/authorities among these agents that influence decision making and may influence the transformation process, (c) understanding how budgets and strategies can be defined to shape resource use and rights allocation toward SPaC-based trade and industrial development in the key areas of water, natural resources, energy, and environment, (d) understanding how relevant sectoral policies can be formulated that indicate the priorities (technical, institutional, and political) regarding sustainable development and economic development, (e) understanding the extent to which the existing policies and processes have relevance to SPaC, and (f) understanding the time-boundedness of SPaC outcomes.

The second phase of mainstreaming focuses on identifying country-specific priority areas and opportunities regarding SPaC. A consideration to social, environmental, and economic developmental priorities is helpful in weaving national-level SPaC programs. The specific issues to be explored involve understanding (a) the priority areas regarding SPaC in other similar countries, (b) in which areas SPaC would be most difficult or easiest to implement, (c) the extent to which discontinued/completed policies address the targeted SPaC priorities, (d) which processes in the existing production-consumption system are under ongoing transformation, and can provide a space for SPaC oriented change, (e) the status quo in the country regarding resource production and consumption, trade flows, and research and development, and (f) the forecast regarding future production and consumption trends in regards to the growing population in the country.

The third phase of mainstreaming requires assessing the institutional and capacity needs within specific industrial sectors in the backdrop of governmental and political contexts. It is specifically important to understand the strengths and weaknesses of existing institutions and capacities in constraining or promoting SPaC. This can reveal a picture regarding the scope of futuristic capability developments, and the available support of businesses, industries, and consumers.

The fourth phase of mainstreaming focuses on identifying and engaging champions to raise awareness and building partnerships in regards to SPaC. This can be achieved through workshops, one-on-one meetings, field visits, media campaigns, etc. Champions can be primarily comprised of representations from the broader stakeholders such as government, NGO, media, civil society, and consumer bodies. They may also involve influential decision-making authorities at the local, regional, national, and sectoral levels for example government officials, key members of business associations, prominent industry figures, academic scholars, and international agencies. Champions are needed to be engaged across the industrial sectors to propagate SPaC as a legitimate business agenda. It is however important to ensure the thorough mentoring and training of champions in regards to SPaC.

The fifth phase of mainstreaming revolves around the setting of formal mechanisms to facilitate sustained mainstreaming. Establishment of a 'leading institution' is a vital step in this regard to demonstrate a strong strategic buy-in toward SPaC. This role can be fulfilled by institutional bodies such as the Ministries of Finance, Planning, and Environment or the Office of Presidency. Another step may involve the establishment of 'steering committee' to ensure multi-body representation to guide the mainstreaming efforts. The sectoral level initiatives can consider establishing 'task teams' possessing specialized domain knowledge to

enhance the reach of mainstreaming. These mechanisms need to target developing common management frameworks regarding technical assistance, work plans for mainstreaming, and timely monitoring/reporting of progress in mainstreaming efforts. It is important for the reporting to be based on qualitative and quantitative data for example industrial production-consumption records, material flow accounts, input-output balances, eco-efficiency/resource efficiency data, and trade data.

The strength of mainstreaming efforts governs the emergence of explicit policies and strategies to guide the SPaC transformation among firms and consumers. The policies can be understood as the formal inclusion of SPaC agenda in the budget of government to facilitate explicit provisions regarding SPaC efforts. The critical aspects involve (a) availability of financing sources for firms to support SPaC, (b) firm's access to knowledge regarding SPaC implementation in terms of technical advisory support, twinning cooperation between firms and national/international organizations, formal training etc., (c) formal inclusion of SPaC agenda in the education system, and (d) institutional cooperation mechanisms between the public and private sector through the definition of new positions and roles based on SPaC.

Furthering from the linkage between mainstreaming efforts and the emergence of policy frameworks, the strategic scope of SPaC also focuses on further explicit mechanisms to ensure SPaC transformation at the systems level.

Incorporating SPaC in design thinking

The strategy of 'Design for Sustainability' focuses on incorporating systematic changes in design thinking to foster sustainable patterns in production and consumption. This can be achieved by focusing on enhancing the functionality, innovation, life span, and resource efficiency of products and services by considering environmental, social, and economic aspects (Niinimäki and Hassi, 2011).

The design of sustainable products incorporates guiding principles that ensure a long product life cycle, product attachment, emotional satisfaction, customization, halfway products, modular structure, co-creation, and open source design.

The lifecycle of a product can be lengthened by radically restructuring the product inputs based on sustainable and high-quality materials. Accommodating such restructuring however demands a relook into production processes through innovative approaches (recycle, re-use, source reduction, etc.) and high ethical values (waste management, sustainability accounting, ethical labor practices, etc.). Design considerations that seek to augment the characteristics of product attachment and emotional satisfaction among users are helpful in facilitating extended consumption of products. Selection of product attributes that remain meaningful to consumers over an extended period of time is important in this regard. A way to achieve an emotional connection between the product and its user involves the strategies of customization and mass customization. These strategies are helpful in empowering the user in a limited frame of choices for example color and style to create a personalized product.

The extent of user involvement in product design and production can be further increased through the concept of the half-way product. This concept relies on the principle of design for easy disassembly. Products can thus be offered as kits to demand the participation of users in translating their personalized creativity and significant assembly efforts. Doing so improves the user knowledge regarding the product, and the ability to repair the product when needed. The modular structure is another variation in this line of design thinking. It focuses on the production of products based on disintegrated modules that can be easily assembled, disassembled, and repaired. Co-creation and open source design emphasize the mass-level participation of end consumers in the product design process. While the co-creation involves seeking design inputs from a limited scope of target consumers, the open source design seeks design inputs from the users worldwide.

Sustainability in services can be achieved through systematic design considerations that facilitate intensive and longer utilization of a product-service system. The first important aspect is to explore competitive ways that would prompt consumers to purchase functions rather than products. This involves considerations such as questioning the relevance of product ownership, high-quality service experience, user-friendliness, shared usage, a non-profit network for sharing/lending/exchange among consumers, renting/leasing, and innovative options that replace goods with services. The service thinking inherent in these considerations demands thorough involvement of the service provider in understanding the vital attributes of consumer satisfaction. This understanding is helpful in improving sustainability performance and product utilization flexibility. Second, apart from the orientation of maximizing consumer value, service design must offer good product performance without increasing waste streams.

However, the achievement of sustainability in design thinking is critically dependent on the collaborative efforts between producers and consumers to generate new knowledge on SPaC transition. Education thus forms the vital aspect of knowledge building in this regard.

Educating for SPaC

Strategic educational interventions focusing on enhancing the knowledge of stakeholders on SPaC are helpful in strengthening the linkage between producers and consumers toward a multi-stakeholder alliance (Petry et al., 2011).

Educating organizational actors about SPaC is an elemental intervention focusing on engaging corporations as learners and educators. This can be achieved through training programs, workshops, and knowledge symposiums to facilitate enabling inputs on SPaC. A further emphasis involves facilitating sector-specific know-how on the incorporation of SPaC practices. For example, the apparel and textile industry can focus on understanding various SPaC practices that can facilitate long-lasting apparels and improve sustainability performance. These focuses can be facilitated by systematically aligning the educational programs around new skill building and creating change agents. New skill building emerges from knowledge on systems and life cycle thinking, social and technical innovations, material reduction, sustainable grades of materials, recyclability and reusability, extended product lives, waste treatment and reduction, collaborative inter-firm action, and energy efficiency. Change agents rely on approaches

such as communication for leading the SPaC agenda, engaging stories, changing perceptions on business outcomes, setting new aspirations, and societal responsibility.

Another educational intervention regarding SPaC focuses on creating innovation-oriented social learning networks. The awareness and adoption of sustainable technologies can be achieved through social arrangements which integrate multiple stakeholders in a common platform. For example, in the Netherlands, several challenges are organized based on the teamwork of stakeholders such as companies, universities, schools, and local communities. One such challenge is the 'Frisian Challenge' which intends to build capacity for solar business development in the region. This challenge engages social teams into the construction and race of solar-powered boats. The inherent social learning framework is helpful in enhancing the sustainability awareness of masses. It also facilitates the exchange of knowledge and technical expertise, the formation of newer alliances, new experience, and new outcomes such as business ideas to promote solar energy.

Further educational intervention approaches focus on the aspects of the development of standards or certification systems to facilitate 'cradle-to-cradle' business systems, development of sustainable communities, and formal incorporation of sustainability agenda through SPaC in b-school curriculums. Standards or certifications facilitate explicit guidelines and documentation requirements to coordinate various intra- and inter-firm processes in the frame of sustainability. Industrial standards for example environmental management systems, food safety standards, social sustainability standard of fair trade can be considered as preliminary steps in this regard. Future developments into certifications must focus on sustainability in an integrative manner to consider the production and consumption along the social, environmental, and economic fronts. Development of sustainable communities can be achieved through promoting resource sharing and trade of used products. Innovative means for example web-based applications, portals are helpful in this regard. Incorporation of the sustainability agenda based on SPaC in b-school curriculums more profoundly contributes to the development of responsible managers and future leaders.

The radical scope of shifts in the transitional pathway of SPaC relies on newer ways of organizing businesses. It is therefore important to focus on how business models can be better aligned with the SPaC paradigm.

SPaC-oriented business models

The paradigm of SPaC is elemental in facilitating sustainable products and services in the contemporary business environment. Conceptualizing business models that enable SPaC to create distinct value for the product/service offerings is the necessary prerequisite.

The newer business models can propagate from the two classic strategic orientations that govern the operations of a firm in the business environment (Wong *et al.*, 2016). While the 'low-cost' strategic orientation focuses on creating products and services that are available to customers at competitive prices, the strategic orientation of 'differentiation' emphasizes on distinguishing the firm's offerings from that of competitors in terms of innovation, speed, flexibility, and quality. Low-cost products and services can benefit from SPaC by modeling business practices around aspects of resource efficiency, shared consumption, buy-back, remanufacturing, and so on. Differentiated offerings, on the other hand, can better respond to the market competition by creating innovative products and services – that are produced through advanced SPaC principles and provide a unique value to consumers by establishing a market niche. Furthermore, the strategies can be hybridized in a product-service system by setting low cost based SPaC as the production agenda, and differentiated service based on SPaC as the consumption agenda.

Scenario building plays a vital role in the selection of an appropriate strategy by the firm to carve SPaC based products and services. This involves system analysis where it is important for the firm to locate key factors that may influence the efficacy of its operations for example market competition, bargaining power of suppliers/customers, firm's internal competence, access to newer business opportunities, complexities, and stakeholder resistance to change. These inputs can better guide the development of future options by systematically considering the aspects such as the importance of self-sufficiency in the society, extent of consumerism, economic growth, and social exclusion (Lorenz and Veenhoff, 2013). Scenario building can be conducted at the local, regional, and global levels to understand the attributes that would govern the demand and supply of sustainable products and services. These considerations also form the inputs regarding the selection of 'SPaC enabling mechanisms' (as noted) for governing the strategic orientation of the business model (Haake and Jolivet, 2001; Lebel and Lorek, 2008).

Another key issue concerns to effectively distinguish the sustainable products and services in the market and convey its unique value to the consumers. This can be achieved by institutionalizing sustainability meta labeling that certify the nature/extent of SPaC sophistication the offering has undergone (Dendler, 2014). An effective sustainability meta labeling scheme is easy to institutionalize, conveys the positive sustainability outcome, distinguishes itself from other labeling schemes in terms of its key emphasis to social and environmental issues, stringency and sophistication of production processes, specific and easily revisable to be adapted to local conditions, and easily aggregates a large amount of information. The acceptance of a labeling scheme among the consumers can be enhanced by focusing on (a) procedural legitimacy which delineates the legitimacy of production process, (b) knowledge legitimacy which highlights the extent to which the labeling extends scientific facts based on research and development, (c) charismatic legitimacy which outlines the extent to which the labeling is supported by trusted organizations in the society, and (d) regulatory legitimacy which characterizes the extent of engagement of government actors in the conceptualization of labeling.

The ultimate focus of a SPaC-based business model is to evolve as a governance mechanism for guiding the creation of sustainable supply chains by integrating the chain of buyers, suppliers, and customers along the principles of SPaC. SPaC is

instrumental in setting the guiding agenda for sustainable supply chain management by defining the scope of sustainable product (and service) portfolio, selection of appropriate business partners (suppliers and customers) to form a supply chain, selection of appropriate SPaC enabling mechanisms to define explicit practices to be implemented throughout the supply chain (Niesten and Lozano, 2015; Roy and Singh, 2017). SPaC is therefore a strategic notion to define the length and breadth (or sophistication) of sustainable business practices to be primarily incorporated by a firm and secondarily incorporated by its supply chain partners. However, the notion of sustainable supply chain management operates as dedicated literature in the domain, and deals with in-depth operational issues, surrounding the coordination of sustainability performance of the supply chain through sustainable business practices (refer. Roy *et al.*, 2018b). Apart from these aspects, the strategic intent of SPaC further extends to operational issues to guide the pathway of SPaC implementation.

The Operational Issues

The operational front of SPaC implementation primarily concerns developing practical approaches to realize the SPaC-oriented shift in firms. Apart from the development of sustainable practices, this front also focuses on addressing operational challenges to facilitate the implementation of sustainability practices in business or organizational routines. The following describes these aspects in greater detail.

SPaC practices

The SPaC practices are explicit protocols that specify a SPaC-oriented shift in the traditional production-consumption practices of firms. They can be simply understood as the operational definition of SPaC enabling mechanisms (Section “The Rationale of Sustainable Production and Consumption”) for reflecting the conceptual space of amalgamation of production and consumption perspective in business practices. SPaC practices are categorized under four heads to reflect diverse firm-level practices (Barber, 2007). Production-oriented practices focus on incorporating changes in production processes to realize sustainable products and reduce resource consumption. For example, industrial ecology practices, cleaner production practices, lifecycle analysis, extended producer responsibility, integrated product policy, safety and health standards in production workspace, modifying product design, source reduction, waste management, sustainability management standards, sustainable supply chain management practices etc. Consumption-oriented practices focus on raising awareness and changing consumption behavior of consumers through approaches such as consumption behavior and trend analysis, consumer information, educating consumers, right-to-know, consumer awareness campaigns, product boycotts, need analysis, etc.

Distribution-oriented practices aim to coordinate the flow of products and services through approaches for example ethical advertising, ethical sales, ethical packaging, ethical pricing, responsible trade, labeling, etc. Investment-oriented practices aim to influence private or public decisions to coordinate investments for achieving SPaC through approaches such as government procurement, sustainability taxes, subsidy reform, investment guidelines, socially responsible investment, and financial institutions reforms and so on. These approaches are evolving and further developments are desired in the area of how more innovative practices can be defined to operationally translate the SPaC enabling mechanisms.

Operational challenges

The key operational challenge concerns bridging the knowledge gap for linking SPaC practices to traditional business protocols. As such, incorporation of SPaC practices in the firm’s routines creates newer and unprecedented conditions to demand significant efforts of firm-level stakeholders toward adaptation (Preuss and Walker, 2011). For example, production processes to facilitate the reuse of input materials demand an upgraded expertise of operators in terms of innovative response for remodeling the explicit and tacit production protocols regarding reuse. Adaptation toward SPaC is therefore dependent on knowledge generating efforts of firm’s stakeholders to innovatively redefine the explicit and tacit knowledge bases of businesses – for successfully accommodating the targeted SPaC practices in the firm’s routines. Innovative responses to SPaC must however fulfill the key elements of products and services, and must be easy to reproduce and replicate. This demands an understanding of consumers in their own context by employing multi-stakeholder processes based on the involvement of local and non-business actors (e.g., NGOs).

The more operational challenges in the production phase includes upgrading the performance management systems to measure SPaC benefits, monitoring costs, customer’s urge on low cost and quick delivery, technical feasibility of innovative responses to SPaC, price competition prevailing in the market, unsuitability of traditional technology, initial investment toward technology upgrade, lack of internal firm resources and capabilities, lack of financial resources, trade-off between mass production and innovation, lack of supply chain infrastructure, complex coordination with inter-firm partners on SPaC, lack of top management commitment, lack of corporate strategy toward SPaC, conflicting sustainability targets and design requirements, and lack of guidance frameworks to guide employees operational decisions. The consumption phase involves the challenges regarding unclear stakeholder responsibility toward SPaC, lack of viable end-of-life recycling framework to integrate consumers, difficulties in reusing/recycling mixture of materials, lack of expertise in remanufacturing, and lack of consumer support in coordinating rising consumption (Tseng *et al.*, 2013; Pallaro *et al.*, 2015; Dubey *et al.*, 2016).

Discussion

Realizing SPaC in business systems is a multifarious agenda involving intricate processes at the strategic and operational levels. These processes are intended to produce radical shifts by reorienting the existing business practices toward sustainability. Given the wider scope of actions involved, it is important to ensure the interconnectedness and complementarity between the strategic and operational aspects of SPaC implementation. Thus, the critical agenda is to mitigate the discrepancy between the intended and actual outcomes in the pathway of SPaC implementation processes (Berg and Hukkinen, 2011). This can be better achieved by thorough monitoring of SPaC progress based on the multi-stakeholder framework. The government's role in monitoring the nationwide progress toward SPaC forms an important focus in this regard (Gandenberger *et al.*, 2011; Kielin-Maziarz, 2013). Future developments need to explicate how policy frameworks can be created around monitoring of SPaC progress through stimulating partnerships among businesses, state of inter-firm relationships, influencing and gauging the state of consumer choice in regards to sustainability, and stimulating and sustaining the behavioral change of firms and masses toward SPaC.

From the firm's perspective, it is important to understand how strategic and operational difficulties in the pathway of SPaC can be mitigated. From a strategic viewpoint, it is important to understand how innovative business models can be developed around SPaC. It is also important to understand how SPaC philosophy can serve as a guiding mechanism to shape more sustainable supply chains. Presently, these literatures lack connect to develop more holistic perspectives regarding the interaction of sustainable development agenda and roles of businesses and consumers. Conceptually, sustainable supply chain management (SSCM) focuses on the strategic development of inter-firm sustainability coordination among businesses to maximize the social, environmental, and economic value of the supply chain. SPaC, on the other hand, is a much broader concept to outline the roles and accountability of wider stakeholders such as governments, businesses, and consumers for ensuring a sustainable future. In the backdrop of the linkage between SPaC and SSCM, the firm-level purview of SPaC is responsible to experiment with business practices and innovative sustainable approaches for enabling SPaC at the intra-firm level. SSCM draws on sustainable business practices and further extends on how such practices can be employed to meet the performance frontiers in the contemporary business landscape. The SPaC knowledge can thus facilitate vital inputs to the SSCM view in terms of different sustainable business practices a supply chain can seek to implement at the chain level (Roy and Singh, 2017; Roy, 2018; Roy *et al.*, 2018a,b).

The operational aspect of SPaC therefore needs to focus on how innovative business practices can be developed to translate the notion of SPaC in firm-level practice. It is important to understand how operational challenges can be mitigated through structured approaches by prioritizing the areas of gradual action in terms of domains such as production/consumption of products and services, design, usage, and disposal. Further approaches can focus on financing innovative implementation, capacity building activities, market-based instruments to attract the attention of producers and consumers, and life cycle thinking.

Overall, the business perspective of SPaC concerns with how the standalone fronts of production and consumption can be amalgamated to generate more profound actions for guiding the sustainable development agenda in the business environment. The key aspects inherent in the notion of SPaC concern the conceptual interpretation surrounding the integration of production and consumption fronts, strategic issues, and operational issues to enable the paradigm.

Introduction

The history of the application of cementitious materials dates back to the period of the Romans. However, with the progress of time, there have been substantial changes in the manufacture, development, and production of concrete. The compressive strength of concrete is generally used as an indicator of quality, which is relatively easy to measure. Knowledge based on extensive studies about how to manipulate the composition of concrete to achieve the desired compressive strength is readily available. However, knowledge relating to other attributes of the composition of concrete is still inadequate and therefore engineers/scientists are actively working on this. Another challenging issue which remains, is to address continuous concrete deterioration due to aging, corrosion, exposure due to aggressive environments. Hence, with the further progress of time, research shifted towards improving the durability of concrete structures. To address these issues higher strength concrete (HSC) applications became popular, which are also a preferable choice in constructing heavily loaded compression members of tall buildings. However, the necessity of a workable mix further inhibited the productivity of HSC. This led to the development of superplasticizer, which enabled engineers to achieve high strength at good workability. Achieving high strength requires high cement content with a tremendous increase in the cost. Apart from this, it has also been realized that just achieving high strength will not be sufficient to achieve the required durability. This necessity proposed utilization of industrial by-products having pozzolanic properties to achieve high strength and durability. Today, with the combined application of mineral and chemical admixtures (superplasticizers), it is possible to obtain high performance in concrete in terms of strength and durability, which is known as high-performance concrete (HPC).

HPC is an engineered concrete whose mix is tailored by adopting low water to binder ratio, and optimal aggregate-to-binder proportion with the incorporation of mineral admixtures and superplasticizers to achieve more workability, high strength, and high durability. HPC possesses one or more of the following characteristics, which can be: (i) low- heat of hydration, porosity, water-binder ratio, bleeding, plastic shrinkage ratio, permeability; or (ii) high - early age strength, workability, and resistance to chemical attack. The following section describes the methodology in selecting materials and design mixes for sustainable production of HPC (Swamy, 1996; Aitcin, 1998; Mehta, 2004; Al-Hadithi and Alani, 2018).

Materials Selection for Conventional HPC

It is necessary to get the maximum performance out of all materials involved in producing concrete. When attempting to produce HPC, any material incompatibility may be detrimental to the finished product. High-performance concrete will contain not only Portland cement, aggregates, and water, but also superplasticizers and supplementary cementing materials. The desirable details of the material properties for production of HPC is given here.

Cement

The basic principle for designing HPC mixes is replacement or substitution of cement by supplementary cementitious material (SCM) with minimal or absence of tri-calcium aluminate, tri-calcium silicate, and di-calcium silicate. The particle size distribution and shape of alternate SCM should be selected similarly to that of the cement to control the rheology of the mixes. The selected cement should develop strength with age and facilitate rheological properties during fresh state. The chemical composition of cement should have a little amount of Tri-Calcium Aluminate (C3A) preferably in cubic form, this helps in enhancing the reactivity of cement and improves the quality and rate of production of ettringite. To impart strength in the cement Tri-Calcium Silicate (C3S) should be fairly present and cement should be finely grounded. It should be noted the presence of soluble sulfate in cement is very important for the selection of cement for HPC. The finer particles hydrate rapidly than coarse particles and hence enhance the early age strength of concrete. But this may also cause loss in workability due to the higher dispensation of heat of hydration. A suitable particle size distribution is to be established so that both the workability retention over a longer period for fresh concrete and higher early age strength is simultaneously achieved.

Fine Aggregate and Coarse Aggregate

The proper selection of fine aggregate becomes very important as rise in target compression strength, makes aggregates weakest location to inhibit failure. Coarser sand corresponding to a fineness modulus range of 2.7–3.0 is preferred over finer sand, as finer sand will require more water and hence lead to workability and segregation issues. The sand packing density should be designed to achieve minimum void ratio; as higher void content will require more water. Another important ingredient for achieving HPC is

coarse aggregate. The incorporation of coarse aggregate leads to the reduction in drying shrinkage and improves permeability of concrete against any ingress of moisture. Coarse aggregates of larger size have less specific surface and hence preferred over smaller size coarse aggregate to attain high workability. Similarly, equidimensional aggregates or cubic aggregates also produce stronger and better mix compared to HPC mixes with flat and elongated aggregates.

Water

The quantity of water required for HPC should be designed and limited to the amount required for binding activity of the hydrated cement gel, as any excess water would lead towards the formation of undesirable voids and capillaries causing the reduction in strength and durability of hardened concrete. In general, the water qualified for drinking purpose is as good for the production of concrete. However, tests should be conducted to check whether the initial hydration rate of cement is affected by the presence of salt in water.

Materials Selection for Sustainable HPC

One of the alternative ways for sustainable production of HPC is the application of industrial by-product as cement replacement or incorporation of superplasticizers for enhancing workability and durability (Shi *et al.*, 2011). The details of the materials are listed hereafter:

Fly Ash

It is a pozzolanic material and produced as an industrial by-product during combustion of coal. Physical properties of fly ash differ from the quality of coal utilized for combustion and appear as spherical, hollow and angular-shaped. Chemically fly ash is classified as Class F (low calcium) and Class C (high calcium). Class F fly ash is produced by combustion of anthracite or sub-bituminous coal while Class C fly ash is produced by burning lignite or bituminous coal. This is also grouped as silicoaluminous (Class F), silicocalcic (Class C) and sulfocalcic group based on the high presence of sulphur and an equal amount of calcium and sulphur, respectively (Wang *et al.*, 2017).

Ground Granulated Blast-Furnace Slag (GGBS)

The reaction between iron oxide, fluxing stone and coal in the blast furnace during the manufacture of pig iron produces slag as the by-product. When the slag is cooled slowly, crystalline shaped aggregates are formed which is utilized as aggregate for concrete, road or embankments. But if the slag is quenched in water immediately after its production, it solidifies into vitreous form and after proper grinding, it attains cementitious properties. It is to be noted that the temperature at which slag is quenched is very important because at higher temperature only vitreous nature is observed and it becomes more reactive. The quality of GGBS can be evaluated easily by subjecting the samples to X-ray diffractogram, where a definite peak of melilite is observed. The slag as binder component is blended with cement after grinding or intergrounded in the clinker. The incorporation of slag reduces heat of hydration, improves pore structure, increases permeability against chemical attack and resistance against sulfate, chlorides, and water. It should be also noted that as the w/b ratio is decreased, the incremental intrusion plot shifts towards the lower range of pore size, macrocapillaries reduces while microcapillaries and gel pores increases. The threshold diameter is also reduced due to the addition of fly ash/slag (Biskri *et al.*, 2017).

Silica Fume

It is a by-product obtained from the manufacture of silicon metal and silicon alloys. The amount of silicon dioxide in the silica fume is greater than 90% and 85% when fabricated from silicon metal and ferrosilicon alloys, respectively. The silica fume is a very fine particle of spherical shape, size ranging less than 1 μm in diameter. The specific gravity of the material is 2.2 and possesses a specific surface area of 15000–25000 m^2/kg compared to the specific surface area of cement being approximately 1500 m^2/kg . The extreme fineness of silica fume causes filler effect and makes it a natural location for germination of crystals of calcium hydroxide, while amorphous nature and high amount of silicon dioxide make it a very reactive pozzolanic material.

Super plasticizer: The selection of proper superplasticizer is very important for dispersing the cement particles adequately to achieve high performance. They are classified into melamine, naphthalene, lignosulfonate and polyacrylates based superplasticizers. In general naphthalene based superplasticizers are preferred due to higher solids content, better control on the rheology and are cost effective. However, to evaluate the performance of compatibility between the cement and superplasticizer it is advised to conduct mini-slump and the Marsh cone tests. Mini-slump method requires less material compare to Marsh cone test but the predicted results are indicative of a static behaviour compared to the more dynamic condition in marsh cone test. The superplasticizer is also responsible to improve the filler effect between cement and other particles such as silica fume.

Mix Design of High Performance Concrete

The main parameters influencing the proportioning of normal concrete mixes are water/cement ratio, cement content, aggregate/cement ratio, size and shape of aggregate etc. However, the conventional methods of obtaining mix proportions for normal concrete cannot be extended due to HPC due to the application of cement replacement materials (CRM) or supplementary cementitious material (SCM). It should be noted that mineral admixtures having pozzolanic properties are known as CRM when utilized as replacement of cement while SCM when incorporated to mix as an addition to the cement. For the design of sustainable HPC, the existing ACI method is modified and the inclusion of the efficiency factor for mineral admixtures is adopted. The efficiency factor (k) is an equivalent factor which on multiplication with the mass of fly ash (f) or selected CRM is equivalent to the mass of cement. Hence the water (w)/cement (c) ratio is replaced with water (w)/binder(b) ratio and designated as $w/(c + kf)$. The steps are as follows (Bharatkumar *et al.*, 2001, 2005):

Methodology I

Step I - Selection of reference mix: For this step well established ACI method is adopted to obtain mix (without superplasticizer) having a slump in the range of 25–50 mm with a w/b ratio of 0.50. If the mix is not having proper workability, the quantity of fine and coarse aggregate is altered, by maintaining the same w/b ratio and aggregate/binder ratio.

Step II - Selection of water content: The obtained ratios in step I is used to cast mixes (three to four number) having reduced water content levels. The workability of the mixes is improved by the addition of superplasticizer. Further charts can be developed to obtain the relationship between the price of superplasticizer plus cement with respect to decrease in water content. The desired optimal water content is selected from the comparison charts.

Step III - Selection of efficiency factor: The efficiency factor is calculated from linear regression method using the strength values obtained without CRM and with CRM. The equations are further modified with respect to replacement level percentage and given by efficiency of mineral admixture ($k(t,p)$). With the help of evaluated efficiency factor compressive strength relation with effective w/b ratio is obtained using the selected materials.

Step IV - Final mix design: After finalization of w/b ratio for the target compressive strength mix proportion of all the ingredients (cement, aggregate, mineral admixtures, the dosage of superplasticizer) can be calculated.

Three sets of mix design results with varying mineral admixture contents are presented. The mix design adopts the concept of efficiency factor for designing. The properties of the binder and coarse aggregate is given in Tables 1 and 2, respectively. The fine aggregate passed 4.75 mm sieve size and have specific gravity and fineness modulus as 2.62 and 2.48, respectively. A sulphonated naphthalene formaldehyde type SP is chosen for the current study.

Set 1

The cement replacement levels in set1 mixes consisted of (i) fly ash – 15%, 25% and (ii) slag 15%, 30%, and 50%. The experimental results of the adopted reference mix are given in Table 3. In the next step Abram's law arbitrary constants $A1$ and $A2$ as per Eq. (1) is obtained. In the next step, linear regression is conducted between $A2$ and the age in days (t) to obtain Eq. (2) using experimental values given in Table 4. After substituting Eq. (2) in Eq. (1), Eq. (3) is obtained which gives the relation between the compressive strength versus c/w relationship for mix with mineral admixtures. Where, $S(t,p)$ and $k(t,p)$ are the strength of HPC and efficiency of mineral admixture, respectively, at the end of t days and for a replacement level p percentage by weight of binder (i.e., $f/(c + f)$), c , w , and f are the cement, water and CRM content in unit volume. $k(t,p)$ can be obtained after further simplification and given by Eq. (4).

$$S = A1(c/w) + A2 \quad (1)$$

$$A2(t) = B1(t/28)^{B2} \quad (2)$$

Table 1 Properties of binder materials

Properties (%)	Cement			Fly ash	Slag
Silica	19.11			58.8–59.1	33.67

Properties	12.5 mm	20 mm
Specific gravity	2.71	2.68
Dry rodded unit weight (kg/m ³)	1550	1700
Water absorption (%)	0.5	0.4

Table 3 Details of mix proportions and concrete properties for two extreme values of w/c (with OPC only, Set-1)

Mix designation	Unit	AO	BO
Water/cement ratio		0.50	0.35
Cement	(kg/m ³)	340	486
Fine aggregate		819	684
Coarse aggregate		1054	
Water		170	
Wet density		2340	2417
SP (% by weight of binder)		0.50	
Slump (mm)	mm	20	25
Compressive strength (MPa) at age of			
3		23.86	57.10
7		29.20	63.67
28		40.93	75.07
56 and		44.52	79.51
90 days		45.52	79.64

Mix designations:

First letter A or B denotes $w/b = 0.50$ or 0.35 respectively.

Second letter O denotes OPC mix.

$$S(t, p) = A1(c + k(t, p)f)/w + B1(t/28)^{B2} \quad (3)$$

$$k(t, p) = (1/f) \left\{ -c + w(S(t, p) - B1(t/28)^{B2})/A1 \right\} \quad (4)$$

For evaluation of efficiency factor $k(t, p)$ of mineral admixtures (fly ash 15% and 25%, and Slag 15%, 30%, and 50%), in mixes for w/b ratios of 0.5 and 0.35, coarse aggregate content and water content is kept constant. The fine aggregate content is revised to achieve similar volume of concrete per unit mass by. No volume adjustment is applied for application of slag, as the specific gravity of slag is similar to cement. The concrete mix proportions and the compressive strength at various ages are given in **Table 3**.

From these strength results, the values of $k(t, p)$ are obtained using the relationship given in **Eq. (4)**. The average values of the efficiency factor obtained for the material investigated and the replacement level used are given in **Table 5**. The main advantage of this method is the use of operating water content based on the effectiveness of the superplasticiser, cost of superplasticiser and cost of cement, whereas existing methods arbitrarily reduce the water content by 5%–10% when SP is added. The proposed method uses the efficiency factor evaluated for the given set of materials to obtain the compressive strength vs effective w/b ratio relationship, which will be used to calculate the effective w/b ratio required for any desired compressive strength, whereas the existing methods use the relationships given in the codes of practice and if the compressive strengths are not close to the desired value, then mix is reportioned for different w/b ratios. The existing methods require a large number of trial mixes to arrive at a mix having minimum cement content, while in the proposed method based on the effective binder values, various combinations of cement and mineral admixtures can be obtained to have mix with minimum cement content.

Set- 2

Set 2 consists of concrete mixes with 20% and 40% cement replacement levels by fly ash while 50% and 70% of cement replacement by slag. The reference concrete mix proportion is given in **Table 6** while mixes with CRM is given in **Table 7**. The obtained formulation for efficiency factor and values is given in **Eq. (4)** and **Table 8**, respectively.

Set- 3

Set-3 consists of concrete mixes with 50% cement replacement by slag. The reference concrete mix proportion is given in **Table 9** while mixes with CRM is given in **Table 10**. The efficiency factor $k(t, p)$ is found to be 0.58, 0.85, and 0.91 at 7, 28 and 56 days for $p = 0.5$.

Methodology II

One of the other popular methods for production of HPC using ACI 363 Committee on high-strength concrete is described hereafter. The first step is to select required strength and slump. The target to be achieved is 25–50 mm without superplasticizer. The second step is to select the maximum size of the coarse aggregate (MSA) depending upon the target strength. For concrete grades having strength less than 65 MPa, 19 or 25 mm size aggregates are recommended. Similarly, for achieving strength greater than 85 MPa aggregate sizes of 10–13 mm and for concrete strength lying in the range of 65–85 MPa, 25 mm aggregates of good quality are

suggested. In the third step the dry weight of coarse aggregate content is evaluated by multiplying the dry-rodded unit weight (%) and dry-rodded unit weight. The formula is applicable for sand having fineness modulus between 3.2 and 2.5. In the fourth step the amount of water is calculated by assuming the entrapped air content between the voids of aggregates. The next steps are to select the water/ binder ratio based on the required strength at 28 and 56 days and cast trial mixes with full or partial replacement of cement using absolute volume method. Finally based on the results of trial mixes amount of fine and coarse aggregate, water, cement,

cementitious material (fly ash, silica fume, GGBS), superplasticizer dosage is redesigned to achieve required physical and mechanical properties. The results of the HPC mixes obtained as per the ACI method are given for ready reference of the readers in **Tables 11–16**, and described here after (Peter *et al.*, 1999; Rajamane *et al.*, 2003; Gopalakrishnan *et al.*, 2005).

Recent Trends for Sustainable Production of HPC

There are two methods for sustainable production of HPC. One method is application of mineral admixtures as binder and other method is application of alternative aggregates. Calcium sulfoaluminate (CSA) cements is found to be one of the promising

candidate as an alternative binder. CSA generally require smaller amount of limestone compared to production of cement and hence reduces carbon dioxide emission. Due to its higher porosity it also improves grinding. High volume slag is another methodology to propel the substitute for cement. It enhances workability, toughness, chemical and corrosion resistance while at the same time also decreases water absorption, pH value, and chloride ion penetration. Apart from mineral admixtures rice husk ash having pozzolanic properties produced HPC with higher compressive strength, at low water/binder ratio with marginal loss in elastic modulus and Poisson's ratio. However, it is also found that rice husk ash mixes have more cracking at lower stress levels and hence may cause brittle failure. In other studies, it found that ceramic waste power can be used up to 20%–30% replacement of

cement. The obtained HPC have lower early age strength but similar strength at the age of 28 days when compared with conventional HPC with ceramic waste. However, from microstructural studies it is found that the ceramic waste does not participate in the hydration reaction and acts as filler (Prem *et al.*, 2018a).

As aggregate replacement in HPC artificial aggregates such as steel slag or crystallized slag is found to increase the strength and durability. However, it should be noted that the mix should be judiciously designed to account for higher specific gravity of this aggregates compared to limestone aggregates. Steel slag aggregates increases strength due to their high strength and better adhesion between cement and paste. The durability parameters are however found to lower in case of water porosity and gas permeability. Few studies also highlight incorporation of polyethylene terephthalate or PET waste in HPC as sand replacement. PET aggregate changes failure mode from brittle to ductile with a reduction in compressive strength. The tensile, flexure strength are found comparable to HPC without PET while durability performance against freeze and thaw resistance is enhanced significantly. In

other studies, fine and coarse recycled concrete aggregate are utilized as alternate aggregate for HPC. It is observed that heat treated recycle aggregates significantly improves physical properties of HPC. The ductility of HPC is also improved by addition of steels fibers, basalt fibers, polypropylene fibers and hybrid fibers

The Way Forward

With more demand of high performance concrete, stringent durability requirements and necessity to obtain low maintenance concrete, currently research have progressed towards development of Ultra high performance concrete (UHPC). UHPC is one of the emerging concrete materials having compressive strength greater than 150 MPa, very high durability and ductility. The concept of HPC have now changed towards UHPC. Recently several industries have commercialized UHPC and its application can be found in form of bridge decks, buildings, precast applications and several niche applications ([Prem *et al.*, 2015, 2018b](#)).

Sustainable Supply Chain Management in Developed vs. Emerging Economies: Evidence From the UK and China's Manufacturing Industry

Ali Esfahbodi and Yufeng Zhang, University of Birmingham, Birmingham, United Kingdom

Introduction

Over the past few decades, rapid industrial modernization has led to increasing negative environmental impacts, including various types of pollution, emissions, waste and chemical spills (Carter and Easton, 2011). In response to the growing global environmental concerns, sustainable supply chain management (SSCM) has emerged as a concept that combines elements of corporate environmental management and supply chain management and aims to promote sustainability-related issues along the intra- and inter-firm management of the upstream and downstream supply chain (Tseng *et al.*, 2015).

Today, organizations are consistently attempting to integrate environmental practices into their strategic thinking and minimize the environmental impact of their operations, as a consequence of pressure from regulatory bodies, heightened customer expectations and competitors (Zhu *et al.*, 2013). With increasing concern about environmental sustainability issues on a global scale, firms' reputation along with their stakeholders' value will be at risk if they are unable to demonstrate a rational position on sustainability (Sarkis *et al.*, 2010). The current sustainability agenda is pushing manufacturing industries to extend their focus beyond traditional economic goals to more broadly address and embrace the environmental and social aspects of the supply chain (Seuring and Müller, 2008a; Gimenez *et al.*, 2012). In light of this, many organizations have begun to adopt sustainability-related supply chain initiatives to manage the environmental and social responsibility of their business operations beyond their immediate organizational boundaries (Carter and Easton, 2011). As a result, SSCM has become a pivotal research theme in the management literature, which has explored the incorporation and management of sustainability-related issues encompassing the environmental, social and economic domains throughout the supply chain (Varsei *et al.*, 2014).

This has generated significant attention within industry, academia, and policy-makers and has become a widely topical particularly with respect to the manufacturing context (Lai *et al.*, 2013). The manufacturing sector is deemed to be the main polluter and resource consumer, as it has been traditionally associated with higher-than-average resource consumption, waste generation and lower implementation of environmental management practices (Zhu *et al.*, 2013). With respect to developed economies, the on-going environmental sustainability agenda, predominantly driven by institutional pressures (Govindan *et al.*, 2014), more pressingly urges manufacturing firms operating within the developed market to take environmental concerns into consideration and accept the necessity of environmental management (Jayarama and Avittathur, 2015). This has led a growing number of manufacturing firms within the developed market to undertake proactive environmental initiatives across their supply chains (Hollos *et al.*, 2012). However, the increasing emphasis on sustainability is not just a phenomenon of the developed world. In emerging economies, manufacturing firms have also started to pay attention to various environmental programmes within their supply chain, as they have faced tighter environmental restrictions from their governments and intense scrutiny from an increasingly educated society and also more environmentally friendly emerging competitors (Esfahbodi *et al.*, 2016).

In view of this, manufacturers in emerging markets have started to adopt various proactive and boundary-spanning SSCM practices – sustainable procurement, sustainable production, eco-design, sustainable distribution, and so forth – in order to minimize the impact of their operations on the natural environment, alleviating scarcity of resources and environmental degradation in these countries (Tseng *et al.*, 2015; Jia *et al.*, 2018). This not only enables manufacturing firms in emerging markets to meet their domestic expectations, but also permits them to compete in the global market, because they conform to international legislation (Esfahbodi *et al.*, 2016).

Economic performance has traditionally been, and continues to be, the key priority for almost all organizations, irrespective of their market orientation, in developed and emerging economies (Zhu and Sarkis, 2007; Green *et al.*, 2012a). Arguably, this is largely associated with the fact that the recognition of financial benefits gained from environmental initiatives in firms' bottom line is crucial for the adoption of such environmental initiatives (Gimenez *et al.*, 2012). It is therefore critical for firms to consider the impact of SSCM adoption on both their environmental performance and their business performance. However, the adoption of SSCM practices is traditionally associated with the hope of mitigating environmental damage while achieving financial performance gains (Rao and Holt, 2005).

While prior research has explored the relationships between the adoption of SSCM practices and firm performance, reporting positive impacts on both environmental and economic performance (Zhu and Sarkis, 2007; Vachon and Klassen, 2008; Lee *et al.*, 2012), recent emergent studies have started to throw doubt onto this issue, offering mixed views (Green *et al.*, 2012a; Esfahbodi *et al.*, 2017). Recent studies conducted in developed economies (Hollos *et al.*, 2012; Green *et al.*, 2012b) have found that the adoption of SSCM does not necessarily lead to better financial performance, arguing that the implementation of SSCM practices is not always both environmentally beneficial and commercially viable. Thus, there is a degree of ambiguity within the existing literature on the developed economies concerning the merits of undertaking SSCM practices as to whether they can deliver both environmental improvements and economic benefits (Hollos *et al.*, 2012; Seuring and Müller, 2008a). Similarly, there is concern within the current literature on the emerging economies as to whether the adoption of SSCM practices will ultimately translate into improved financial performance

(Rao and Holt, 2005; Zhu *et al.*, 2013). Therefore, this study is deemed an important complement to the prior research on SSCM implementation and its commensurate performance gains conducted in developed economies and emerging markets as well.

Although research on sustainable supply chains in developed economies has made many valuable contributions (Green *et al.*, 2012a; Hollos *et al.*, 2012), there is a paucity of empirical evidence and theoretical reflection on characteristics of SSCM in developing and emerging economies (Govindan *et al.*, 2014; Jayarama and Avittathur, 2015). Concerning the impact of SSCM adoption on firm performance, much research has been conducted in developed economies. The SSCM literature concerning emerging economies is in the early stages of development, with related articles dealing primarily with theoretical discussions and anecdotal evidence (Hsu *et al.*, 2013), calling for further empirical investigation. Accordingly, the goal of this study is to enhance the understanding of how sustainability-related issues of supply chain can impact firm performance in both emerging and developed economies. It therefore endeavors to bridge the existing gap surrounding the lack of empirical evidence concerning SSCM adoption in the context of emerging economies together with the lack of consensus on this topic.

Furthermore, despite recent developments in the literature, more empirical research is needed to establish the impact of SSCM practices on firms' performance outcomes, particularly from a holistic and integrated perspective (Green *et al.*, 2012b). It is necessary to view the phenomenon from the whole supply chain perspective, covering both upstream and downstream aspects, which allows a thorough and rigorous picture of SSCM implementation to be captured (Carter and Easton, 2011). Thus, this study also aims to extend the contemporary literature with a better and more comprehensive understating of SSCM and its main components and their impacts on firms' environmental and economic performance.

In order to bridge the aforementioned gaps in the literature and advance the contemporary understanding of sustainable supply chains, this research seeks to investigate integrated SSCM Practices → Performance Outcomes relationships. Adopting the UK as a developed economy and China as an emerging economy enables this study to draw comparative conclusions on these two different markets. The value of a cross-economy empirical comparison of SSCM adoption within two different markets is that it will help to distinguish potential similarities and contradicting directions within developed and emerging economies. This study therefore provides a general comparative analysis of SSCM adoption along with its performance gains, with a focus on similarities and differences between these two economies, in order to consolidate our understanding.

The remainder of this paper is organized as follows: Section "Literature Review and Hypothesis Development" presents a literature review and develops the hypothesis, Section "Research Method" presents the research method along with a summary of the samples and data, Section "Results" presents the results, Section "Discussion" outlines theoretical implications of the study and Section "Conclusions" concludes the paper.

Literature Review and Hypothesis Development

Sustainable Supply Chain Management (SSCM)

SSCM has become an increasingly important topic in the current literature, owing to various factors supporting its acceptance and favouring its adoption such as tighter governmental regulations, social pressures, competitive pressures, heightened customer expectations, the scarcity of natural resources and corporate image (Govindan *et al.*, 2014). Environmental sustainability and pollution are global concerns that affect manufacturing industries in both developed and developing countries (Esfahbodi *et al.*, 2016). According to Beamon (1999), "waste generation and natural resource use, primarily attributed to manufacturing, contribute to environmental degradation". These increasing global issues indicate an imperative need for manufacturing firms to realign their strategies and operations to address sustainability-related issues along the upstream and downstream supply chain.

The SSCM approach aims to 'close the loop' by including the implications of reuse, remanufacturing, and recycling of products and materials in a common forward supply chain (Zhu *et al.*, 2008c) with the purpose of minimizing negative environmental impacts and wasted resources, from the acquisition of raw materials up to the final use and disposal of products (Hsu *et al.*, 2013). This study defines SSCM as the management of raw materials, components and processes from manufacturers to suppliers to final customers along with the product being taken back through the lifecycle stages with the purpose of having the lowest possible negative environmental impact (Hu and Hsu, 2010; Esfahbodi *et al.*, 2016).

According to contemporary literature, pressure from a variety of stakeholders and institutional pressures are the main driving forces that have pushed manufacturing firms to pursue and undertake SSCM practices in the developed economies, and recently in emerging economies as well (Jayarama and Avittathur, 2015). Consequently, manufacturing firms have begun to implement a set of SSCM practices to minimize the negative environmental impacts associated with the entire lifecycle of their products or services, starting from design through the acquisition of raw materials to consumption and product disposal (Lai *et al.*, 2013). Today, the SSCM approach has evolved to include boundary-spanning activities such as sustainable procurement (Carter and Carter, 1998), eco-design (Zhu *et al.*, 2008a), sustainable distribution (Vachon and Klassen, 2006), and investment recovery (Zhu and Sarkis, 2007). Given the multi-dimensional expansion of the SSCM literature, this study focuses on four major SSCM practices: sustainable procurement, eco-design, sustainable distribution and investment recovery. These four areas represent the full implementation of SSCM practices, as they encompass the main upstream and downstream activities and sustainability-related operations within the supply chain (Zhu *et al.*, 2013).

SSCM Practices and Performance Implications

Previous research has explored the links between the implementation of SSCM practices and performance outcomes, including operational, environmental, and economic performance (Green *et al.*, 2012a; Zhu *et al.*, 2013; Esfahbodi *et al.*, 2017). Existing literature has offered significant insights into the potential for sustainable supply chain initiatives to achieve strong environmental improvements (Rao and Holt, 2005; Zhu and Sarkis, 2007; Green *et al.*, 2012a), supporting positive impacts on environmental performance. However, opinions on whether SSCM practices cause or relate to positive or negative economic performance are still mixed (Tseng *et al.*, 2015). While Rao and Holt (2005) indicated that greening the supply chain delivers economic benefits leading to improved financial performance, Green *et al.* (2012a) suggested that benefits from SSCM practices are not being reaped in terms of short-term profitability and financial performance. Therefore, there is a degree of inconclusiveness on the relationships between SSCM practices and performance outcomes within the existing knowledge in this area that necessitates further empirical investigation. This study primarily focuses on the environmental and economic dimensions of SSCM performance, mainly due to the dearth of recorded relevant and validated social performance measures within the SSCM context (Varsei *et al.*, 2014).

This study seeks to examine whether UK and Chinese manufacturing firms perceive improvements in both their economic and environmental performance due to the adoption of SSCM practices. In essence, Chinese manufacturer are at a relatively early stage of adopting sustainability-related supply chain initiatives, which may leave more room for further development and improvement (Lai *et al.*, 2013). In the UK, however, manufacturing firms have been practising SSCM initiatives for a longer period, approaching SSCM piecemeal and therefore better performance implications have more precedent (Esfahbodi *et al.*, 2017). For example, the European Union has enacted various Environmental Directives such as Restriction of Hazardous Substances (RoHS), Energy-using Products (EuP), Waste Electrical and Electronic Equipment (WEEE), End of Life Vehicle (ELV), and so forth, which have led manufacturers to minimize negative environmental impact (Grote *et al.*, 2007). Such international regulatory policies not only push UK manufacturers to undertake environmental initiatives across their supply chains, but also force manufacturers in developing countries which intend to export and sell to Europe to embark upon the adoption of SSCM practices (Sarkis *et al.*, 2010; Esfahbodi *et al.*, 2017).

Among the various SSCM initiatives that have been implemented by UK manufacturing firms and also adopted by Chinese manufactures, specific importance has been placed on four fundamental practices: sustainable procurement, eco-design, sustainable distribution and reverse logistics (Esfahbodi *et al.*, 2017). In the context of UK and Chinese manufacturers, each initiative represents the extent to which each firm in these two countries engages in sustainable supply chain practices. While the four major SSCM initiatives are not unique to the UK and China, and are prevalent in other emerging and developed economies including Germany, France, Australia, India and Brazil, they represent a strong commitment that these countries' governments had made through their strategic environmental plans to focus on such initiatives to foster SSCM approaches (Jia *et al.*, 2018).

SSCM Practices-Performance Model

This study developed a structural model linking the main SSCM practices to firm performance. The relationships between SSCM practices and environmental and economic performance are posited in order to assess the impact of SSCM implementation on the firm's performance. The structural model is a path analytical framework with six latent variables (shown in Fig. 1): sustainable procurement, sustainable distribution, eco-design, investment recovery, environmental performance and economic performance. The four SSCM practices represent the main sustainability-related operations within the upstream and downstream supply chain, while environmental and economic performance cover performance outcomes (Zhu *et al.*, 2008a; Esfahbodi *et al.*, 2016). Each of the hypotheses depicted in Fig. 1 is theorised as being direct and positive. Definitions of the variables incorporated in the model are presented in Table 1. Generally, SSCM practices are the focal constructs in the structural model, with environmental and economic performance as consequences.

Fig. 1 SSCM practices-performance model.

Table 1 Construct definitions

Construct	Definition
Sustainable procurement (SP)	Sustainable procurement focuses on cooperating with suppliers for the purpose of developing products that are environmentally sustainable (Zhu <i>et al.</i> , 2008a).
Sustainable distribution (SDIST)	Sustainable distribution refers to the environmentally conscious transportation of products or services from suppliers to manufacturers to final customers with the purpose of having the least possible negative environmental impact (Esty and Winston, 2009; Green <i>et al.</i> , 2012b).
Eco-design (ED)	Eco-design requires that manufacturers design products that minimize the consumption of materials and energy, facilitate the reuse, recycling and recovery of component materials and parts, and avoid or reduce the use of hazardous products within the manufacturing process (Grote <i>et al.</i> , 2007; Zhu <i>et al.</i> , 2008a).
Investment recovery (IR)	Investment recovery refers to the process of recovering and recapturing the value of end-of-life products and unproductive assets through effective reuse and surplus sales. It requires the sale of excess inventories, scrap and used materials and excess equipment (Zhu <i>et al.</i> , 2008a).
Environmental performance (ENV)	Environmental performance relates to a manufacturing plant's ability to reduce energy usage, materials consumption, air emissions, effluent waste and solid waste and to decrease consumption of hazardous substances and toxic materials (Zhu <i>et al.</i> , 2008a).
Economic performance (ECN)	Economic performance relates to the manufacturing plant's ability to reduce costs associated with energy consumption, purchased materials, waste treatment, waste disposal, waste discharge, and fines or penalties for environmental accidents (Zhu <i>et al.</i> , 2008a).

Sustainable supply chain management practices and environmental performance

The majority of recent articles have argued that SSCM practices can improve environmental performance in most cases (Rao and Holt, 2005; Vachon and Klassen, 2006; Zhu and Sarkis, 2007). In particular, recent studies have tended to agree on a positive relationship between sustainability-related supply chain initiatives and environmental performance (Hollos *et al.*, 2012; Green *et al.*, 2012b). The main SSCM practices of sustainable procurement, sustainable distribution, eco-design, and investment recovery are environmentally friendly initiatives by nature, which are designed to minimize a product's environmental impact without creating a negative trade-off with other performance dimensions, such as costs and functionality (Green *et al.*, 2012a). This is also in line with Porter and Van der Linde's (1995) argument for a balance between a society's desire for environmental protection and the economic burden on industry. The implementation of each individual SSCM practice is deemed to have direct environmental results, as measured by reductions in air emissions, effluent waste, solid waste and the consumption of toxic materials (Zhu and Sarkis, 2007; Seuring and Müller, 2008b). Therefore, the implementation of sustainable procurement, sustainable design, sustainable distribution, and investment recovery is expected to result in improved environmental performance due to their capability to reduce material consumption, waste, emissions, energy usage, and excessive inventory (Zhu and Sarkis, 2007; Seuring and Müller, 2008a).

According to Carter and Carter (1998) and Zhu *et al.* (2008a), sustainable procurement requires working closely with suppliers to develop products or services that are environmentally friendly. Suppliers' involvement is crucial in improving firms' environmental performance, as it is the suppliers who are capable of ensuring the purchased materials are environmentally friendly and have been made using environmentally conscious processes (Hsu *et al.*, 2013). In supporting this, Vachon and Klassen (2008) argued that, in the manufacturing context, strong relationships and collaboration with suppliers aid the adoption and development of innovative environmental technologies. Hollos *et al.* (2012) also asserted that cooperating with suppliers, partnership agreements and joint research and development lead to improvements in environmental performance. Considering the main aim of sustainable procurement, cooperating with suppliers that possess green resources, capabilities, and expertise required for the acquisition of environmentally friendly inputs in order to develop environmentally friendly products or services (Esfahbodi *et al.*, 2017), a positive relationship between sustainable procurement and environmental performance is proposed.

Sustainable distribution deals with environmental issues related to sustainable transportation, packaging, warehousing, storage maintenance, inventory control, and facility location allocation decisions that aim to have the least possible negative environmental impact (Sarkis, 2006). Sustainable distribution is developed specifically to improve environmental performance as it focuses on the elimination of emissions associated with the transportation of products throughout the supply chain (Green *et al.*, 2012b). Green packaging characteristics such as materials, shape, and size, play an important role in sustainable distribution, because of their impact on transportation, e.g., carbon footprint implications (Zhu *et al.*, 2008c). Firms can benefit from better packaging along with rearranged loading patterns as this can increase space utilization in the warehouse and reduce materials usage and the amount of handling required, leading to improved environmental performance (Esty and Winston, 2009). Lakshmideera and Palanisamy (2013) also asserted the environmental benefits of the sustainable distribution practice, particularly with respect to the design of the logistics network, highlighting options such as central warehouses or distributed networks, direct shipping or hub-and-spoke, third-party services or private fleet, and intermodal or single mode.

Eco-design, the most significant sub-attribute of sustainable manufacturing (Green *et al.*, 2012a), aims to design and develop a product or a service with environmental considerations, minimizing negative environmental impact (Grote *et al.*, 2007). Eco-design practice facilitates the reduction of the negative environmental impacts of products with the design characteristics of lower material usage and energy consumption in the product development (Seuring and Müller, 2008a). According to Green *et al.* (2012a), eco-design can potentially improve environmental performance, as the impetus of the designers will be towards reducing

the environmental impact of the design. Eco-design practice largely focuses on the elimination of wastes associated with environmental sustainability across the supply chain (Zhu *et al.*, 2008a). Arguably, such waste minimization should deliver environmental improvements leading to better environmental performance.

Investment recovery, the last construct of the SSCM practices, generally involves the task of recapturing the value of unused products or unproductive assets through effective reuse or surplus sales and divestment (Zhu *et al.*, 2008a). The practice of investment recovery, a sub-attribute of reverse logistics (Lai *et al.*, 2013), has the potential to deliver environmental benefits with its focus on recovering and recapturing the value of unused or end-of-life assets (Green *et al.*, 2012a). In a manufacturing setting, investment recovery draws in reuse and surplus sales of used materials, which should eventually lead to a decrease in the emissions and waste generated by by-products (Zhu *et al.*, 2008a). Thus, with this set of arguments, this study postulates the following hypotheses.

- H1. Sustainable procurement directly and positively impacts environmental performance.
- H2. Sustainable distribution directly and positively impacts environmental performance.
- H3. Eco-design directly and positively impacts environmental performance.
- H4. Investment recovery directly and positively impacts environmental performance.

Sustainable supply chain management practices and economic performance

The main focus of SSCM practices is on the elimination of wastes associated with material acquisitions, product design, delivery and disposal (Green *et al.*, 2012a; Esfahbodi *et al.*, 2017). Arguably, such waste minimization should yield cost reductions, leading to better economic performance. Prior studies have shown that environmental management programmes such as sustainability-related supply chain initiatives have a positive relationship with firm financial performance (Rao and Holt, 2005). According to Tan *et al.* (2014), SSCM practices can enhance corporate reputation, brand image, and customer satisfaction, which can in turn bring improved economic performance. The majority of existing studies conducted in the sustainable supply chain context have argued that SSCM practices are positively related to economic performance, given their cost-saving nature (Rao and Holt, 2005; Sarkis, 2006; Zhu *et al.*, 2012). Furthermore, Sarkis *et al.* (2010) argued that success in addressing environmental issues may provide new opportunities for competition and new ways to add value to core business programmes. Therefore, the implementation of SSCM practices is expected to result in better economic performance due to their potential for cost reduction.

Undertaking sustainable procurement facilitates the acquisition of environmentally friendly inputs, which in turn eliminates associated wastes and emissions (Carter, 2005). Arguably, cost reductions associated with such waste minimization should lead to improved economic performance. Moreover, firms can benefit from a range of tangible and intangible green purchasing cost savings features, for example, in minimizing risk occurrences that can potentially damage its product image (Shi *et al.*, 2012). It has been further argued by Shi *et al.* (2012) that green purchasing can help manufacturing firms to achieve long-term savings by protecting them from potential damage to their brand value. Rao and Holt (2005) also maintained this and demonstrated a positive linkage between adopting green purchasing and economic performance through empirical investigation. The same can be argued about sustainable distribution which aids the minimization of energy and emissions associated with transportation throughout the supply chain, which in turn can result in effective cost savings. Hollos *et al.* (2012) found a significant direct linkage between sustainable distribution and financial performance. Their results suggested that the benefits of green packaging and green logistics characteristics can be reaped in long-term profitability.

Eco-design can positively influence economic performance due to its significant cost-saving features that stem from the capability of reducing material usage and energy consumption at the design stage. Eco-design requires manufacturers to minimize the consumption of materials and energy required for the whole cycle of product development, which can potentially lead to reduced costs associated with material and energy consumption, delivering economic benefits (Esty and Winston, 2009). Moreover, the waste minimization focus of eco-design practice is expected to lead to reduced costs associated with waste treatment or waste discharge, affecting economic performance (Green *et al.*, 2012a). Rao and Holt (2005) supported this proposition and demonstrated a significant direct linkage between eco-design and financial performance, reporting that the SSCM practice of eco-design has the capacity to enhance economic performance and lead to competitiveness. Investment recovery can also have an impact on a firm's economic performance, as it involves surplus sales of scrap and used materials, and capital excess equipment (Green *et al.*, 2012b). Zhu and Sarkis (2007) found a linkage between investment recovery and financial performance and reported that investment recovery has the capacity to affect economic performance through effective surplus sales and divestment. Therefore, this study hypothesizes the following:

- H5. Sustainable procurement directly and positively impacts economic performance.
- H6. Sustainable distribution directly and positively impacts economic performance.
- H7. Eco-design directly and positively impacts economic performance.
- H8. Investment recovery directly and positively impacts economic performance.

Research Method

Survey Development

Zhu *et al.* (2008a) developed and empirically verified a measurement model for SSCM practices and their commensurate performance constructs. They found four underlying variables which reflect the key dimensions of SSCM practices along with performance measures of environmental and economic performance. The present study directly adopted these measurement items

of Zhu *et al.* (2008a) for the Sustainable Procurement and Investment Recovery constructs. For the Sustainable Distribution and Eco-Design measures of Zhu *et al.* (2008a), this study utilized additional items found in other studies (Esty and Winston, 2009; Green *et al.*, 2012b). These measurement items were operationalised in a survey questionnaire to assess the environmental and economic performance consequences of the implementation of SSCM. Respondents were asked to evaluate the implementation of individual SSCM practices, using a five-point Likert scale ranging from 1 = no implementation to 5 = implemented fully. In addition, a five-point scale for evaluating the significance level of performance improvement due to the adoption of SSCM practices was provided, ranging from 1 = not at all to 5 = significant.

Samples

The constructs incorporated into the proposed model were defined and described with a focus on the manufacturing context. Considering this manufacturing focus, data was collected from a sample of manufacturing managers working for UK and Chinese manufacturing firms. Anticipating the difficulties associated with recruiting knowledgeable and experienced respondents, the convenience sampling technique was employed to target managers with knowledge of their firm's SSCM practices and environmental and economic performance (Malhotra and Grover, 1998). The questionnaire was administered using convenience sampling to a sub-set of the population of manufacturing managers, e.g., plant managers, industrial waste managers, logistics managers, purchasing managers, engineering managers, supply chain managers, operations managers, and sales managers.

Data Collection

The surveys were conducted via a Web-based survey service (Bristol Online Surveys) from March 2014 to April 2014 and data was collected from 218 managers of various manufacturing firms, 146 in the UK and 72 in China. The data collection process was managed by Bristol Online Surveys and was structured so as to ensure unique responses from validated employees of UK and Chinese manufacturers. A total of 600 managers were contacted via email for the UK survey, 36 were screened out as non-managers and 194 managers completed the survey. Of the 194 respondents, 48 selected the 'other manager' category. Because of concerns related to a lack of sufficient understanding of SSCM practices and environmental and economic performance, data from these 48 was not included in the dataset analyzed. Finally, data from 146 manufacturing managers who have the necessary knowledge to fully complete the survey was included in the UK dataset that is subsequently analyzed. With respect to the China survey, of the 600 individuals sent email requests to participate, 42 were screened out as non-managers and 110 managers completed the survey. Of the 110 respondents, 38 selected the 'other manager' category, which were excluded in the Chinese dataset due to concerns

Table 2 Sample's demographics summary

<i>Title</i>	<i>UK number</i>	<i>China number</i>
Plant Manager	16	8
Logistics Manager	19	10
Operations Manager	28	14
Purchasing Manager	13	9
Supply Chain Manager	36	16
Sales Manager	11	7
Engineering Manager	17	5
Industrial Waste Manager	6	3
<i>Total</i>	<i>146</i>	<i>72</i>
<i>Industry classification (UK SIC – Standard Industrial Classification)</i>		
Manufacture of Food Products	14	6
Manufacture of Beverages	6	9
Manufacture of Textile	1	5
Manufacture of Rubber and Plastics Products	2	10
Manufacture of Wood and of Products of Wood and Cork	5	4
Manufacture of Paper and Paper Products	8	7
Manufacture of Chemicals and Chemical Products	17	5
Manufacture of Basic Metals	12	3
Manufacture of Electrical Equipment	23	7
Manufacture of Machinery and Equipment	14	4
Manufacture of Motor Vehicles, Trailers and Semi-Trailers	42	7
Manufacture of Basic Pharmaceutical Products and Pharmaceutical Preparations	2	6
<i>Total</i>	<i>146</i>	<i>72</i>
Mean years in current position	6.85	8.26
Mean number of employees	594.62	638.62

related to a lack of knowledge of SSCM practices and performance. Subsequently, data from 72 manufacturing managers who have the necessary knowledge to complete the survey was included in the Chinese dataset. [Table 2](#) displays the sample's demographics.

All of the respondents hold management positions in manufacturing firms. The majority of respondents are operations and supply chain managers, 43% for the UK sample and 40% for the Chinese sample. The respondents selected 12 different industry classifications representing a diverse array of manufacturing firms. They work for firms with an average of 594.62 employees for the UK sample and 638.62 employees for the Chinese sample. According to [Gimenez et al. \(2012\)](#), firms are classified as large if they have 250 employees or more and small/medium if they have fewer than 250 employees. This research sought to target large manufacturing firms because they are likely to have undertaken some sustainable supply chain initiatives.

Results

Common Method and Non-Response Bias

To ensure avoidance of the common method bias (CMB), procedural control was conducted together with Harman's one-factor statistical test. To avoid 'common rater' effects as one of the key causes of common method bias ([Podsakoff et al., 2003](#)) due to respondents' perceived need to provide consistent or socially desirable answers, options were provided such that respondents could choose to remain anonymous on both the respondent and the company. A confidentiality statement was also included at the beginning of the survey stating that no information of respondents and their companies would be revealed in the study reports. Harman's one-factor test was also used to examine the possibility of the CMB problem. In this test, a principal component factor analysis was performed using the Varimax rotation method with all variables in the proposed model. The results of the factor analysis revealed that three factors explain 70.68% of the variance of the variables with 22.15% explained by the first extracted factor. Based on the recommendation by [Podsakoff and Organ \(1986\)](#), substantial common method bias is signaled by the emergence of either a single factor or one 'general' factor that explains a majority of the total variance. Hence, there was neither evidence that a single factor emerged nor any factor explaining most of the variance. Thus, the common methods bias is not a serious problem with the survey data.

To test for non-response bias, the responses of the early and late waves of the returned surveys were compared, based on the assumption that the opinions of late respondents are representative of the opinions of theoretical non-respondents ([Rogelberg and Stanton, 2007](#)). Respondents were categorised as responding to either the initial or follow-up requests that were sent approximately two weeks later. A comparison of the means of the demographic variables and the summary variables for the two groups of the two samples was conducted using one-way ANOVA. The comparisons resulted in statistically non-significant differences at the 0.01 level. Since non-respondents have been found to descriptively resemble late respondents ([Lambert and Harrington, 1990](#)), this finding of general equality between early and late respondents indicates that the non-response bias has not impacted the data set, suggesting that the non-response bias was not a problem ([Green et al., 2012a](#)).

Scale Assessment

The measurement scales were assessed for reliability and validity. Since all scales were taken directly from prior research ([Zhu et al., 2008a](#); [Esty and Winston, 2009](#); [Green et al., 2012a](#)), content validity was assumed. Following [Gerbing and Anderson \(1988\)](#), each pair of scales under consideration was tested for discriminant validity using a chi-square difference test. Chi-square difference tests for pairings of each scale with other scales returned significant differences at the 0.01 level, indicating sufficient discriminant validity for all scales ([Garver and Mentzer, 1999](#)).

The construct validity of the theoretical constructs was also assessed using exploratory factor analysis (EFA) to "determine whether the majority of the variance can be accounted for by one general factor" ([Podsakoff et al., 2003](#)). As a result of the exploratory factor analysis, the 'Sustainable Procurement' (SP4), 'Sustainable Distribution' (SDIST5), and 'Environmental Performance' (ENV6 and ENV7) measurement items were excluded. Consequently, all of the constructs yield an average factor loading of 0.84, exceeding the recommended 0.70 level, providing evidence of self-reporting scales ([Kline, 1998](#)). This confirmed that all of the remaining measurement items in each construct represent one factor, indicating sufficient construct validity ([Hair et al., 2010](#)).

Furthermore, all standardised coefficients for scale items presented in [Table 3](#) exceed the recommended 0.70 minimum and are significant at the 0.01 level, indicating sufficient convergent validity ([Garver and Mentzer, 1999](#)). All of the reliability coefficients (Cronbach alpha values) for all of the measurement scales exceed the recommended 0.70 level, indicating sufficient reliability ([Garver and Mentzer, 1999](#)). The standardised coefficients for measuring items and their associated t-values along with the Cronbach alpha values for all of the scales are displayed in [Table 3](#).

Measurement Model Assessment

The measurement items were also assessed within the context of the full measurement model using confirmatory factor analysis (CFA), as recommended by [Koufteros \(1999\)](#). For the UK sample, the measurement model fits the data well, with a relative chi-square value of 1.368, a root mean square error of approximation (RMSEA) value of 0.052, a comparative fit index (CFI) value of 0.981, an incremental fit index (IFI) value of 0.988, and a non-normed fit index (NNFI) value of 0.964. Likewise, for the China

Notes: UK: Chi-Square Ratio = 1.368; RMSEA = 0.052; NFI = 0.95; NNFI = 0.96; CFI = 0.98; IFI = 0.98. China: Chi-Square Ratio = 1.742; RMSEA = 0.068; NFI = 0.81; NNFI = 0.91; CFI = 0.92; IFI = 0.92.

sample, the measurement model fits the data fairly well, with a relative chi-square value of 1.742, RMSEA value of 0.068, CFI value of 0.920, IFI value of 0.920, and NNFI value of 0.910.

For both sample groups, the relative chi-square value is less than the 3.00 maximum recommended by Kline (1998) and the RMSEA value is below the maximum of 0.08 (Schumacker and Lomax, 2004). According to Byrne (1998), the Comparative Fit Index (CFI) and Incremental Fit Index (IFI) are more appropriate fit indicators when the sample size is small. The IFI and CFI values for both samples are greater than the recommended 0.90 level (Byrne, 1998). The results concerning the fit of the model generally support a claim of good fit. Table 3 displays the measurement model results along with the model fit indices. All of the t-values of the measurement items exceed the recommended value of 2.575 for both samples and are significant at the 0.01 level, indicating sufficient convergent validity (Byrne, 1998). Furthermore, none of the standardised residuals exceeds the 4.00 maximum recommended by Hair et al. (2010), suggesting that there is no concern regarding a potential unacceptable degree of error.

Structural Equation Modeling (SEM) Results

Multicollinearity was tested by calculating the variance inflation factors (VIF) for each regression coefficient before reporting SEM results. A threshold of a VIF value that is less than or equal to 10.0 is a commonly used criterion to determine the presence of multicollinearity (Hair et al., 2010). The VIF values range from 1.136 to 2.074, significantly below the recommended threshold of 10.0 recommended by Hair et al. (2010), suggesting that multicollinearity does not pose a problem to the proposed model. Furthermore, the correlation coefficients are positive and significant at the 0.01 level for all variable pairings for both samples, except for investment recovery (IR) in the China sample, which is significant at the 0.05 level. The results indicate that there is a

certain degree of association between the variables, permitting further regression analysis. The correlation coefficients are displayed in [Table 4](#).

The proposed structural model was analyzed using partial least squares structural equation modeling (PLS-SEM) provided by the SmartPLS 3.2.6 software. SmartPLS was employed to test the research hypotheses as it is appropriate when the sample size is small ([Chin and Newsted, 1999](#)). According to [Chin and Newsted \(1999\)](#), SmartPLS can provide valid results in the case of a small sample and the minimum threshold of sample size is 10 times the largest number of structural paths directed at a particular construct in the structural model. [Fig. 2](#) illustrates the model with the SEM results specified in the SmartPLS output. The SEM results related to individual hypothesis tests are also displayed in [Table 5](#).

All hypotheses are positive and significant with the exception of H6 (SDIST → ECN), H7 (ED → ECN) for both sample groups and H8 (IR → ECN) for the China sample. For both samples, H1, H2, H3, and H4, which predict a positive association between SSCM practices and environmental performance, are positive and significant as expected, indicating that SSCM implementation in the context of UK and Chinese manufacturers leads to higher levels of environmental performance. However, H5 through H8, which predict positive associations between SSCM practices and economic performance, offer another side to the story: While the link between sustainable procurement and economic performance is significant and positive, eco-design practice negatively impacts on economic performance and sustainable distribution does not impact on economic performance for both samples. Moreover, although the link between investment recovery and economic performance is significant and positive in the UK sample, it does not significantly impact on cost performance with respect to Chinese manufacturers.

The results demonstrate a significant linkage between the implementation of SSCM practices and the environmental performance of manufacturing firms operating in UK and China. However, the results related to the linkage between the adoption of SSCM practices and economic performance is less clear-cut. While there are significant linkages between the implementation of SSCM practices and economic performance through sustainable procurement and sustainable design, there is no significant linkage between economic performance and sustainable distribution for either UK or Chinese manufacturers. In essence, the results suggest that the adoption of SSCM practices leads to higher levels of environmental performance, resulting in environmental improvements, but does not necessarily lead to improved economic performance, as only sustainable procurement is positively and significantly linked to economic performance in both samples.

Discussion

The results show that the impact of the implementation of SSCM practices on performance gains is roughly similar irrespective of the sample group, particularly in relation to environmental performance. Hence, it may well be argued that there are more similarities than differences between SSCM practices and their associated effect on performance in these two different economies. As the model depicts (see [Fig. 2](#)), all of the SSCM practices result in improved environmental performance. This indicates that the adoption of SSCM practices leads to higher levels of environmental performance and greater environmental improvements in both developed and emerging economies on different trajectories, the UK and China, although with different degrees of impact. However, the results surrounding the impact of SSCM implementation on economic performance are less clear-cut. Specifically, the results associated with sustainable design for both samples are contentious, as is that for the investment recovery practice for the China sample, which is different from the UK samples.

Fig. 2 SSCM practices-performance model with results.

In terms of UK manufacturing firms, sustainable procurement positively and significantly impacts on both environmental and economic performance. This can be explained by the fact that the practice of sustainable procurement is focused on decreasing the levels of environmental pollutants. From an economic standpoint, responsibility for sustainable procurement may lie with the supplier rather than the manufacturer, and thus it is potentially less costly for manufacturers to implement than other SSCM practices (Zhu *et al.*, 2008a). The result associated with sustainable procurement for the China sample is roughly similar to that for UK manufactures but with a lower degree of association. This denotes that sustainable procurement is being implemented by Chinese manufacturers and also delivering economic benefits, but to a lesser extent. This can be explained by the fact that the sustainable supply chain approach has only recently begun to emerge in China, and therefore there are few suppliers with green resources and expertise capable of providing environmentally friendly materials or services to manufacturers in China, compared to the UK. Sustainable procurement is considered to be a little more costly in the context of emerging Chinese manufacturers due to the lack of sufficient green suppliers, hindering the achievement of a higher degree of economic performance.

On the other hand, the SSCM practice of eco-design positively impacts environmental performance, and negatively and significantly impacts economic performance within both samples. Such a positive and significant relationship can be explained by the fact that most of the environmental impacts of a product and its processes are 'locked' into the design stage when materials are selected and product performance is largely determined (Grote *et al.*, 2007). The result associated with sustainable procurement for the UK sample is roughly similar to that for Chinese manufacturers, but with a greater degree of association (UK: $\beta = 0.64$, sig. at 0.01 level; China: $\beta = 0.35$, sig. at 0.01 level). This indicates that eco-design is being very well adopted by UK manufacturing firms, delivering improved economic performance to a greater extent compared to Chinese manufacturers. This can be explained by the fact that the SSCM approach, particularly green design-related issues, was introduced to UK manufacturers earlier than to emerging economies and has been put into practice for a longer period compared to China, which has only recently begun to undertake such

Table 5 Summary of hypothesis testing

environmental initiatives. (Grote *et al.*, 2007) argued that the aim of eco-design is to “reduce a product’s environmental impacts without creating a negative trade-off with other design criteria, such as functionality and costs”. It appears, then, that eco-design has not fully accomplished the intended aim in terms of cost performance. This may be because eco-design initiatives require further development and improvement and necessitate more capital investment. In addition, the capacity of eco-design to reduce environmental pollutants is counterbalanced by increases in the associated costs, perhaps related to materials purchases (Green *et al.*, 2012a).

Sustainable distribution directly impacts environmental performance but does not significantly impact economic performance in either sample. This can be explained by the fact that the practice of sustainable distribution is focused on decreasing the levels of environmental pollutants, which has the capacity to enhance the environmental performance. From an economic standpoint, the lack of appropriate infrastructure hinders the benefits of such SSCM practice from being reaped in terms of profitability and financial improvement. This necessitates further infrastructure investment in order to tackle the potential lack of green logistics, resources, and capabilities. Furthermore, green distribution’s capability to reduce environmental pollutants is restrained by increases in associated costs related to the implementation of sustainable distribution initiatives.

While investment recovery positively impacts environmental performance for both samples, it does not significantly impact economic performance for the China sample. Conversely, investment recovery is significantly associated with improved economic performance within UK manufacturing firms. This may be explained by the fact that the practice of investment recovery has received much less attention in China than in developed countries such as the UK (Zhu *et al.*, 2008a). Zhu and Sarkis (2007) found different findings on investment recovery practices and reported that while investment recovery is positively associated with economic performance, it is not significantly associated with environmental performance. The difference in the results may be attributed to differences in the samples employed in terms of size and segments. However, our results are consistent with the findings of more recent work by Green *et al.* (2012a), which solidifies the position of the findings of this research.

Conclusions

The findings of this study suggest that the implementation of SSCM practices results in a higher level of environmental performance in both developed and emerging economies, but may not ultimately lead to improved economic performance, particularly in emerging economies. The results suggest a number of interesting insights concerning the SSCM literature. First, this study developed an integrated SSCM practice-performance model to investigate the relationships between greening the supply chain and performance gains and found a trade-off between environmental and economic performance. Second, the contribution of this research is significant in that it is one of a few empirical studies that have attempted to use diverse samples from both developed and emerging economies on different trajectories, extending the literature on sustainable supply chains in the manufacturing context.

While not all of the individual hypotheses are supported, the theoretical model holds together reasonably well. Furthermore, based on the relative good fit of the theorised model, the model is deemed to be a good representation of the relationships among the research constructs. Using structural equation modeling, the results show that there are more similarities than differences concerning the impact of SSCM implementation on the performance of manufacturers operating in the UK and China. It can be

concluded that the adoption of sustainable practice across the supply chain leads to higher levels of environmental performance for manufacturing firms in both developed and emerging economies, resulting in environmental improvements. However, the study provides evidence that the adoption of SSCM practices in the context of emerging economies does not necessarily lead to improved economic performance, as only sustainable procurement is positively and significantly linked to economic performance.

The results of this research clarify the proposition that SSCM practice is indeed environmentally necessary, but that the benefits might not be being reaped in terms of short-term profitability, particularly within emerging economies. Firms operating in developing countries must undertake environmental initiatives with a broader consideration of the firm's overall economic objectives. In other words, firms need to undertake SSCM practices in a bearable and equitable sense that does not harm their financial bottom line. This promises to allow firms in developing countries to balance existing in a growing economy with environmental protection. Furthermore, this ensures a win-win situation for supply chain partners with green capabilities and minimizes trade-offs between environmental and economic performance. Therefore, this research asserts that a sustainable supply chain can be successfully adopted in emerging economies if it is commercially viable to be able to take a long-term view on the profits gained.

Implications

In terms of practical implications, practitioners are provided with a validated framework for assessing the synergistic impact of SSCM practices on environmental and economic performance. Moreover, the SSCM practices validated in this work can help manufacturing firms operating in developed and emerging economies to identify those areas that require improvement and prioritization in terms of their green efforts. This work can be useful for manufacturing industries that need to convert their traditional supply chain into a more sustainable one. In the resource-constrained environment of the UK and China, the research framework points to the key environmental initiatives in the supply chain that need to be implemented, i.e., sustainable procurement, eco-design, sustainable distribution, and investment recovery. Collectively, the key SSCM practices can serve as an audit tool and later on as a benchmarking tool for managers to evaluate the perceptions of SSCM in their organizations. Developing countries should invest more in appropriate infrastructures that enhance green resources, expertise, and capabilities. This will enable the benefits of sustainability to be reaped in terms of long-term profitability and financial performance in the emerging economy context.

Limitations and Future Direction

Future studies may include the role of SSCM driving forces in the research framework and investigate their impact on SSCM implementation and its commensurate performance gains. Studies on SSCM are still at the early stage in developing appropriate measurements of social performance, particularly in the manufacturing context, and future research may develop and verify social dimension of SSCM performance. To increase the generalizability of this research, repeating this study in different developed and emerging countries will be another research direction. A robust theorization process to outline the boundary conditions around the SSCM practice-performance relationship is recommended for the continuing growth of this body of knowledge. Moreover, future studies may examine other emerging markets to eliminate the potential effect of country-level variance such as market size, economic development, and legal systems. Furthermore, the research sample is limited to large manufacturing firms and therefore, small and medium-sized enterprises (SMEs) are poorly represented. Further research could examine the study's findings using SME samples, conducting comparative research. Lastly, this research has been developed primarily with a focus on manufacturing firms, and little consideration has been given to the service sector. Therefore, future studies may examine the applicability of findings from this investigation for the service sector.

Sustainable Technologies in Agriculture Sector: Ensuring Green Food Production for Resource Conservation

Khalid Zaman, University of Wah, Wah Cantt, Pakistan

© 2020 Elsevier Inc. All rights reserved.

Introduction

The role of agriculture technologies played a vital role to increase food grains and transformed conventional farming to modernize farming, however, its put a burden on natural environment in the form of different anthropogenic activities, including methane emissions, nitrous oxide emissions, carbon emissions, fossil fuel energy consumption and its resulting impact on excessive greenhouse gas (GHG) emissions (Nagothu, 2018). The need of sustainable technologies largely rises that limit global temperature less than 2°C without compromising food security (Frank *et al.*, 2017). The era of globalization largely provoked the need of information and communication technologies (ICTs) that could be used in every walk of economic activities, including technology oriented green revolution, technology driven green supply chain management, technology based green financing, etc. This study considered different ICTs factors for increasing agriculture yield, including broadband subscriptions, telephone subscriptions, computer communications, mobile and internet penetration. The previous studies largely used these ICTs factors in improving agriculture production (see, McDonough, 2012; Jespersen *et al.*, 2014; Irungu *et al.*, 2015; Tzounis *et al.*, 2017; Treinen *et al.*, 2018, etc).

The developed economies largely spend enormous expenditures on research and development (R&D) for increasing sectoral value added. European countries designated high R&D expenditures on regulating economic affairs while these economies largely used sustainable technologies in agriculture sector for massive food production (Olesen and Bindi, 2002; Long *et al.*, 2016, etc). The latest report of European Union (Europa, 2018) emphasized the need of smart solution for sustainable agriculture by smart technologies to reduce pesticides and water consumption for agriculture production. Europa (2016) report confined that new technologies are required more state-of-the-art of R&D in agriculture farming for improving agriculture yield. European seed association (ESA, 2016) discussed the viability of technical solution for sustainable agriculture in the European Union and drafted the report for policy intervention in agriculture farming through innovation and confined that technical solution will provide more sustainable agriculture inputs that improve livelihood of the farmers. The Global Forum for Innovations in Agriculture (GFIA, 2018) conferred the smart food application techniques through technological innovations and its solution in Europe that considered one of the milestones in EU sustainable agriculture farming.

Tilman *et al.* (2002) argued that high pace of population growth possesses serious challenges for sustainable farming and ecosystem that need new policies and incentives for agriculturist to meet the demand of farm yields for environmental integrity. Smith *et al.* (2007) concluded that innovative technologies could improve efficient use of land resources that helpful to eradicate poverty, hunger, and malnutrition, which further translated in to adaptation of global warming policies to mitigate GHG emissions from agriculture sector. Rao (2007) devoted an integrated ICTs framework in agriculture development and confined its importance in increasing agriculture yield. Van Ittersum *et al.* (2008) discussed three viable strategies through which sustainable agriculture system could developed across Europe, i.e., the use of agriculture mechanization to transform primitive agriculture, environmental conservation strategies, and rural support programmes, all these combined to improve agriculture sector contribution at large scale. Koutsouris (2010) critically reviewed the importance of ICTs in rural development and comes to the point that it creates 'digital divide' that linked with urban-rural divide, which create large inequalities in rural sector. Thus, if the problem area is not address with caution, the problem of intra-rural digital divide tends to show in low human development and unsustainable rural development. Horlings and Marsden (2011) found that agriculture and ecological approaches support the gigantic increase in human population to feed, thus it required real green revolution that transformed primitive and old farming techniques in to modernize farming, which required R&D expenditures to convert isolated agriculture food practices in to technology embedded farming. Tschamtkke *et al.* (2012) discussed the global food security challenges that is merely due to feed massive population, while on the same time conservation of biodiversity is compromised due to large agriculture intensification on land, thus the efficient use of land resources devoted for food production should be segregated and/or integrated with wildlife friendly farming, however, the ongoing debate on land segregation and land integration has failed to achieved the stated objectives so far. Andreopoulou (2012) discussed green informatics in environment and sustainability agenda that is connected with number of smart technologies, however, the share of these smart technologies in GHG emissions largely increases to form 'carbon footprint', which need sustainable ICTs instruments for conserving natural ecosystem. Nakasone *et al.* (2014) confined the role of mobile phones penetration in agriculture sector development at macro level, while its impact at micro level still need more policy interventions in order to get desirable results. Adenle *et al.* (2015) discussed the number of constraints that developing countries limitize investment in R&D in appropriate technologies, including, weak land resource reforms, inadequate agriculture research, limited disbursement of credit, and imperfect agriculture technology transfer, these constraints lead to low adaption of climate change. Dodo and Reith (2015) discussed the viability of sustainable computing in agriculture and rural sector development across developing countries and found that solar powered computers is the optimized solution to get access with latest ICTs embedded technology to rural sector which save carbon intensity per year up to 22 kg of CO₂ emissions. Syiem and Raj (2015)

concluded that ICTs are largely penetrated in agriculture base farming where farmers are largely used mobile phones for social communication, health emergencies, inputs availability, information about input quality, management of crops by preventing it from disease, and contacting middle men and experts for marketing and advisory support. Thus, the viability of mobile phones penetration in agriculture farming is assumed to give better payoff in terms of increasing agriculture yield. Luthra *et al.* (2018) considered the importance of internet of things (IoT) based technologies in agriculture supply chain management (ASCM) and confirmed that the application of IoT based technologies are imperative for the promotion of ASCM in a developing countries. Kabbiri *et al.* (2018) extended the technology acceptance model by adding two more constructs, i.e., 'perceived advantage' that users bring mobile phones for farming communications and 'socio-economic characteristics' by which farmer's age, experience, and household head responsibility tend to put in force to use mobile phones for increasing agriculture production. The technology embedded agriculture growth largely decrease digital divide and farmers get received an enormous income by large agriculture production. Petridis *et al.* (2018) found that diffusion of innovation in rural income, export promotion activities, farmer's education, and female employment significantly enlarge that improve agri-food business across countries.

The need of sustainable technologies is the key of economic development and without achieving agriculture transformation from conventional farming to modernize farming; this objective would be a dream for attaining sustainable development. The research questions are based upon the stated theme, which is important for the policy makers to device sustainable policies in order to modernize agriculture without rising global GHG emissions. The first research question is related with agriculture mechanization and agriculture base emissions, i.e., *does agriculture mechanization would improve quality and quantity of food grains without increasing agriculture methane emissions and nitrous oxide emissions?* This question need more attention in order to access the food exported quality and food imported items while its possible impact on natural environment in the form of agriculture emissions. The second question is about the role of ICTs in food production, i.e., *to what extent ICTs may improve the quality and quantity of food production?* This question indicates the efficient use of ICTs in agro-based farming that could improve agriculture production many times from conventional based farming. The final question is all about ICTs impact on natural environment, i.e., *does ICTs may helpful to reduce carbon-fossil emissions by improving agriculture sector through modernizing farm level inputs?* This question would draw policy inferences for the adaptation of modern technology at farm level activities to increase cereal yield with zero emissions. The study has a following key objectives, i.e.,

- (1) To examine the impact of agriculture technology, agriculture CH₄ emissions, agricultural N₂O emissions, high-technology exports, R&D expenditures and insurance and financial services on food exports and imports.
- (2) To examine the role of telephone, mobile, and internet penetration in food production, and
- (3) To analyze the role of ICTs exports in carbon-fossil emissions.

These objectives need fair assessment in order to device sustainable policies for increasing agriculture value added in a panel of selected countries.

This study has a novel contribution in food-environment modeling where ICTs factors mediate in the process to explore its positive impact on food production and environmental conservation policy actions to achieve sustainable development agenda. The previous studies limited to find either the role of ICTs in agriculture production (see, May *et al.*, 2007; Odongo *et al.*, 2013, etc.) or the role of ICTs in environmental sustainability (see, Hilty *et al.*, 2006; Fuchs, 2008; Melville, 2010; Wu *et al.*, 2018, etc.), while the literature is limited to include sustainable technologies in food industry (see, Ruiz-Garcia *et al.*, 2009). The study has a further noteworthy contribution by including, telephone, computer, mobile, and internet penetration in food-environment modeling, which clearly distinguished with the previous literature that add few technology indicators in a given scenario. Besides that, the study used 12 agriculture and resource factors, 4 environmental factors and 7 growth-specific factors, while in total the study explored 29 important factors that determine the impact of sustainable technologies on food industry. The study used sophisticated econometric technique to handle country-specific and time-invariant shocks during the study time period for robust inferences.

Data Source and Methodological Framework

The study used number of promising factors that is associated with three stated models, i.e., Model 1 comprises the nexus between agriculture insurance, R&D expenditures and food production, where food imports (denoted by *fimp*) and food exports (denoted by *fexp*) served as a response variables while agriculture machinery (denoted by *agrmac*), agriculture methane emissions (denoted by *agrch4*), agriculture nitrous oxide emissions (denoted by *agrm2o*), agriculture exports (denoted by *agrex*), agriculture value added (denoted by *agrval*), insurance and financial services (denoted by *ifs*), livestock production index (denoted by *lpi*), and R&D expenditures (denoted by *r&d*) served as explanatory factors. Model 1 comprises two equations, which is represented below, i.e.,

Model 1: Agriculture, insurance, R&D expenditures, and food production

$$fimp_{it} = \beta_0 + \beta_1(agrmac)_{it} + \beta_2(agrch4) + \beta_3(agrm2o)_{it} + \beta_4(ifs)_{it} + \beta_5(r \& d)_{it} + \nu_i + \gamma_t + \varepsilon_{it} \quad (1)$$

$$fexp_{it} = \beta_0 + \beta_1(agrmac)_{it} + \beta_2(agrch4) + \beta_3(agrm2o)_{it} + \beta_4(agrex)_{it} + \beta_5(agrval)_{it} + \beta_6(agrcereal)_{it} + \beta_7(ifs)_{it} + \beta_8(lpi) + \beta_9(r \& d)_{it} + \nu_i + \gamma_t + \varepsilon_{it} \quad (2)$$

where, β_1 to β_9 shows coefficient values of the respective variables, β_0 shows constant value, ν shows country specific shocks, γ shows time specific shocks, i shows 26 countries, t shows time period from 2000 to 2017, and ε shows noise disturbance term.

It is expected that agriculture machinery increases food production that escalate agricultural commodity exports, while its import food technology to improve agricultural value added. The agricultural emissions, i.e., agricultural methane emissions and nitrous oxide emissions would be negative impact on net food exports. It is expected that higher agriculture exports tend to increase food exports, which is further supported by country's insurance and financial services, livestock production, and R&D expenditures. Food imports are expected to increase by higher R&D expenditures and insurance and financial services across European countries. Model 2 is related with information and communication technologies and its impact on food production, which is shown by two given equations, i.e.,

Model 2: Technology and food production

$$fbt_{it} = \beta_0 + \beta_1(fbs)_{it} + \beta_2(fis) + \beta_3(ht\ exp)_{it} + \beta_4(mcs)_{it} + \beta_5(int\ ernet)_{it} + \beta_6(gdppc)_{it} + \beta_7(indvad) + \beta_8(top)_{it} + \beta_9(fdi)_{it} + \nu_i + \gamma_t + \varepsilon_{it} \quad (3)$$

$$fpi_{it} = \beta_0 + \beta_1(fbs)_{it} + \beta_2(fis) + \beta_3(ht\ exp)_{it} + \beta_4(mcs)_{it} + \beta_5(int\ ernet)_{it} + \beta_6(gdppc)_{it} + \beta_7(indvad) + \beta_8(top)_{it} + \beta_9(fdi)_{it} + \nu_i + \gamma_t + \varepsilon_{it} \quad (4)$$

In Eqs. (3) and (4), food, beverages, and tobacco consumption (denoted by fbt) and food production index (denoted by fpi) both served as a response variables, while fixed broadband subscriptions (denoted by fbs), fixed telephone subscriptions (denoted by fis), high-technology exports (denoted by $htexp$), mobile cellular subscription (denoted by mcs), internet penetration (denoted by $internet$), GDP per capita (denoted by $gdppc$), industry value added (denoted by $indvad$), trade openness (denoted by top), and FDI inflows (denoted by fdi) served as explanatory factors. It is expected that information and communication technologies would be a positive impact on food, beverages, and tobacco consumption and food production, which is further mediated by GDP per capita, industry value added, trade openness, and FDI inflows. Model 3 shows the nexus between environmental factors, food production, and ICT in a panel of selected European countries. The model comprises two equations, which are as follows, i.e.,

Model 3: Environment, food production, and ICT exports

$$CO2_{it} = \beta_0 + \beta_1(f\ exp)_{it} + \beta_2(fpi)_{it} + \beta_3(ht\ exp)_{it} + \beta_4(agr\ mac)_{it} + \beta_5(ict)_{it} + \beta_6(chm)_{it} + \beta_7(waste)_{it} + \beta_8(comp)_{it} + \beta_9(gdppc) + \beta_{10}(gdppc)^2_{it} + \beta_{11}(lucp)_{it} + \beta_{12}(lpi)_{it} + \nu_i + \gamma_t + \varepsilon_{it} \quad (5)$$

$$FFUEL_{it} = \beta_0 + \beta_1(f\ exp)_{it} + \beta_2(fpi)_{it} + \beta_3(htexp)_{it} + \beta_4(agr\ mac)_{it} + \beta_5(ict)_{it} + \beta_6(chm)_{it} + \beta_7(waste)_{it} + \beta_8(comp)_{it} + \beta_9(gdppc) + \beta_{10}(gdppc)^2_{it} + \beta_{11}(lucp)_{it} + \beta_{12}(lpi)_{it} + \nu_i + \gamma_t + \varepsilon_{it} \quad (6)$$

In Eqs. (5) and (6), carbon dioxide emissions (denoted by CO_2) and fossil fuel energy consumption (denoted by $FFUEL$) served as a response variables, while food exports, food production index, high-technology exports, agriculture machinery, ICT exports (denoted by ICT), chemical (denoted by chm), combustible renewables and waste (denoted by $waste$), computer communications (denoted by $comp$), GDP per capita, land used for cereal production (denoted by $lucp$), and livestock production index (denoted by lpi) are served as explanatory factors. It is assumed that food exports, food production index, high-technology exports, agriculture machinery, ICT, chemicals, waste, land devoted for cereal production, and livestock production index, all factors would increase high mass carbon emissions and fossil fuel emissions, while computer communication exports and ICT goods exports would decrease high mass emissions in order to support technology free emissions. It is assumed that there would be an inverted U-shaped relationship between per capita income and carbon-fossil emissions, which supported United Nation sustainable agenda across European countries. Table 1 shows the list of variables and its measurement.

The basis of this study is inspired by the latest work of Zaman et al. (2016), which shows some overwhelming fact about European countries for food poverty and food inequality trapped and concluded with the fact that European countries required sustainable policy instruments in order to increase agriculture production. However, this study extends this relationship and includes sustainable technologies in order to increase food grains by agricultural mechanization process. The study collected a data from World Bank (2018) for 26 European countries on the basis of availability of the data. The missing values are in between the sample period of 2000–2017 of the given variables series are filled by preceding and succeeding values of the respective variables for improving degree of freedom. Table 2 shows the sample of countries for ready reference.

The study started with the mechanism of 'Technology Acceptance Model (TAM)' as suggested by Davis et al. (1989), which shows some interactive linkages between the end users and technology adaptation. The users that ultimately intend to adopt the new technology, the number of influential factors act on a same time that either support to use new technology or it negatively averted not to use that technology. The perceived usefulness and perceived ease of use are subject to the most influential factor that may influence the behavior and attitude of the users to actual use the technology.

Table 1 List of variables and its measurement

<i>Factors</i>	<i>Variables</i>	<i>Measurement</i>
Agriculture and food resources	Food, beverages and tobacco consumption	% of value added in manufacturing
	Food production	Index (2004–2006 = 100)
	Food exports	% of merchandise exports
	Food Imports	% of merchandise imports
	Land under cereal production	hectares
	Livestock production	Index (2004–2006 = 100)
	Agricultural machinery	Number of tractors used in agriculture
	Agricultural methane emissions	thousand metric tons of CO ₂ equivalent
	Agricultural nitrous oxide emissions	thousand metric tons of CO ₂ equivalent
	Agricultural raw materials exports	% of merchandise exports
	Agriculture, forestry, and fishing, value added	constant 2010 US\$
Information and communication technologies	Cereal yield	kg per hectare
	Fixed broadband subscriptions	Subscriptions in numbers
	Fixed telephone subscriptions	Subscriptions in numbers
	Mobile cellular subscriptions	Subscriptions in numbers
	Individuals using the Internet	% of population used
	Communications, computer, etc.	% of service exports
Environmental factors	ICT goods exports	% of total goods exports
	CO ₂ intensity	kg per kg of oil equivalent energy use
	Fossil fuel energy consumption	% of total energy consumed
	Combustible renewables and waste	% of total energy waste
Growth-specific factors	Chemicals	% of value added in manufacturing
	GDP per capita	constant 2010 US\$
	High-technology exports	% of manufactured exports
	Industry (including construction), value added	constant 2010 US\$
	Trade Openness	% of GDP
	Foreign direct investment, net inflows	US\$
	Insurance and financial services	% of commercial service exports
	Research and development expenditure	% of GDP

Czech Republic	Ireland	Poland	Spain	

Source: World Bank, 2018. World Development Indicators. Washington D.C.: World Bank.

The study extended the technology acceptance model in an interactive environmental modeling where external factors are represented with ICTs, high-technology exports, FDI inflows, and trade openness, which positively influenced agriculture mechanization process. Agriculture mechanization process is subject to the perceived usefulness and ease of use, which upgrade the technology, however, on the cost of electronic waste in the food production. Thus it suffers the sustainable food production agenda, which is contrary to the mission and vision of United Nation sustainability agenda across countries. Fig. 1 shows the research framework of the study.

The study employed panel regression technique, which is discriminated by Hausman test for model specification. Panel least square regression has serious limitations in terms of handling country-specific and time invariant shocks, which is approached by panel fixed effect and/or panel random effect models. The fixed effect model is given by the following equation, i.e.,

$$y_{it} = \alpha + \beta x_{it} + \mu_i + v_t \quad (7)$$

Y is the dependent variable and x is the set of regressors. μ_i is the white noise error term that affect dependent variable for each cross-sectional unit, while the time specific shocks is shown by v . The least squares dummy variable approach is used to capture the fixed effect model that extend Eq. (7) in a given form, i.e.,

$$y_{it} = \alpha + \beta x_{it} + \mu_1 D1_i + \mu_2 D2_i + \mu_3 D3_i + \dots + \mu_N DN_i + v_{it} \quad (8)$$

where, $D1_i$ to DN_i shows dummy variables that correspond the value of one against its cross-section while zero otherwise.

Fig. 1 Research framework of the study. *Source:* Self extract.

The error component model is an alternative method that proposed different constant terms, i.e., α for each cross-section that are assumed to constant over time. In addition, a stochastic term, i.e., ε_i varies cross-sectionally and it constant over time. The random effects model is as follows, i.e.,

$$y_{it} = \alpha + \beta x_{it} + \omega_{it}, \quad \omega_{it} = \varepsilon_i + v_{it}$$

Where, ε_i has zero mean, v_{it} has constant variance.

The Hausman test is designed to discriminate in between fixed effect model and random effect model. The significant chi-square test confirmed the viability of fixed effect model while insignificant chi-square statistics confirmed the model specification in favor of panel random effect model.

Results and Discussion

Table 3 shows the descriptive statistics of the studied variables. The mean value of agriculture methane emissions and agriculture nitrous emissions are 8382.151 thousand metric tons of CO₂ equivalent and 6737.056 thousand metric tons of CO₂ equivalent respectively. The maximum value of food exports, food imports, agriculture exports, and high-technology exports are 9.471% of merchandise exports, 9.386% of merchandise exports, 2.5009% of merchandise imports, and 10.684% of merchandise exports respectively.

The average value of fixed broadband subscriptions, fixed telephone subscriptions, and mobile cellular subscriptions are 2,870,113, 7,231,192, and 21,116,185 respectively. The maximum value of food, beverages, and tobacco consumption, and chemicals used in manufacturing is about 15.7384% of value added in manufacturing and 10.03285% of value added in manufacturing respectively. The mean value of food production index and livestock production index is about 104.1359 and 101.165, respectively, with a standard deviation of 169.07 and 153.75, respectively. The mean value of land used under cereal production and total cereal yield is about 4,003,523 hectares and 4457.366 kg per hectare respectively with a positively skewed distribution and high kurtosis value. The maximum value of trade openness and R&D expenditures is about 111.1018% of GDP and 1.249% of GDP respectively. The average value of GDP per capita, industrial value added, agriculture value added, and FDI inflows are about US\$26186.3, US\$1.05E + 11, US\$1.01E + 10, and US\$1.52E + 10 respectively with high kurtosis value. The minimum value of tractors used in agriculture is about 5917, maximum value is 1,755,501 and average value is about 324,498.5. The average value of individuals using the internet is 51.697% of population, computer communication is 38.307% of service exports, ICT goods exports is about 5.613% of total goods exports, CO₂ intensity is about 2.295 kg per kg of oil equivalent energy use, fossil fuel energy consumption is about 73.148% of total energy consumed, and combustible renewables and waste is about 8.169% of total energy waste. The positive skewed distribution and high kurtosis value exhibit the data variability on the right hand side of the distribution with considerable peak of the distribution. **Table 4** shows the model specification test by Hausman chi-square statistics.

The results show that Eqs. (1), (2), and (4) has a significant chi-square statistics at 1% level of significance, thus its confirmed that the given equations would used fixed effect regression model, while the remaining equations, i.e., Eqs. (3), (5), and (6) does not fall in the critical region at 5% level of significance, thus these equations would used panel random effect regression model. The results clarify that the given models influenced with country-specific and time-invariant shocks, thus its need sophisticated panel regression apparatus to minimize these shocks for obtaining robust inferences. After specify the panel regression models, the study estimated Eqs. (1)–(6) for parameter estimates (see, **Table 5**).

The results show that agriculture machinery largely increases food production both in terms of food exports and food imports, while its impact is invisible on carbon emissions and fossil fuel emissions during the study time period. The results imply that tractor that are used in agriculture production for harvesting and threshing the crops increases food production, which ultimately

reap economic profit by its exports and imports. Delgado *et al.* (1994) argued that agricultural technology is helpful to interlinked sectoral growth, which is one of the desirable policy options for getting economic incentives via production more food grains to feed massive population growth. Sekhon (2014) concluded that technology has a wider role in order to produce more food grains that could be applied on pesticide and fertilizers for more crop production. The negative impact of agricultural methane emissions on food exported items is visible, which impede agriculture value added. The policies to minimize food export losses by agricultural methane emissions are imperative for sustainable farming. Mosier *et al.* (1998) discussed the mitigation strategies of CH₄ emissions by improving animal productivity and agricultural crops, which is deemed desirable for conservation of natural environment. Saunois *et al.* (2016) found that global CH₄ emissions is rapidly increasing due to biogenic process, which becomes one of the major source of GHG intensive scenarios that need to be limitize by sustainable agriculture policy instruments. Wollenberg *et al.* (2016) emphasized the need to reduce global temperature up to 2°C by adopting sustainable mitigation options related with agriculture based methane emissions and soil carbon. Agriculture nitrous oxide emissions are largely evident during food exports, which need more sustainable agriculture instruments in order to reduce emissions and improve food exports across European countries. Dobbie *et al.* (1999) found that agricultural N₂O emissions chiefly attributed by intensive agricultural fields with increasing soil water- filled pore space, rising temperature, and an increase in fertilizer application on soil mineral nitrous

oxide contents. Tian *et al.* (2015) argued that CH₄ emissions and N₂O emissions both are largely influenced global GHG emissions after CO₂ emissions, however, the intensity to influence on climate change is still unexplored that have a serious impact on ecosystem health. Snyder *et al.* (2014) opined that it is imperative to develop broad based sustainable policies to mitigate N₂O emissions by efficiently used *N* per unit of animal products, land area and per unit crop. The improvement in insurance and financial services should be stronger enough to influence positively on food imports. Xiong (2017) argued that food safety is desirable for imported food items to mitigate food security risks. Was and Kobus (2018) concluded that crop insurance played a vital role in order to received compensation in the past yields that is affected, while its further supported to large food grains, intensification of crop production and improving soil quantity. There is a positive relationship found between R&D expenditures and food imports, as higher the R&D spending on food production, largely it will increase food imports of sustainable agriculture items (see, Hurley *et al.*, 2014). Agriculture sector provides food grains to the economy; therefore, high agriculture exports reduce total food exports due to feed high mass population growth across countries. The positive impact of cereal production on food exports tend to show the valuable contribution of cereal production per hectare in total food exports, which is good sign to earn more economic profits through food items trade (see, Cassman, 1999; Hussain, 2010, etc).

The importance of information and communication technologies in agricultural production is quite visible in terms of agriculture mechanization process that gives an increase in food grains and cereal yields to the economy (see, Rao, 2007; Aker, 2011; Janssen *et al.*, 2017, etc). The two important factors of ICTs are fixed broadband subscriptions and telephone subscriptions that are used here to analyze the impact of telephone and broadband subscribers on the consumption of food, beverages, and tobacco and found positive relationship between them, interestingly, the impact of both the ICTs factors on total food production index is negative, which required more intensive ICTs factors in agriculture production across countries (see, Abu *et al.*, 2017; Aldosari *et al.*, 2017, etc). The impact of high-technology exports on food, beverages, and tobacco consumption is

negative, however, it supports total food production index on the cost of high fossil fuel emissions in a panel of selected countries. The result implies that high-technology exports associated with high fossil fuel emissions simultaneously with high food production that need to make vigilant sustainable policies to reduce fossil footprints from food production (see, [Bauer et al., 2016](#)). The next two ICT factors, i.e., mobile cellular subscriptions and internet penetration are used in food production models and found that mobile cellular subscriptions negatively impact on food, beverages, and tobacco consumption, however, its importance in food production index is largely evident that emphasize the need of mobile cellular penetration in food modeling (see, [Shah et al., 2014](#); [Aker and Ksoll, 2016](#), etc). The results of the study further confirmed the internet penetration in food production index, where internet technology substantially increases food production index across countries (see, [De Silva et al., 2017](#); [Duncombe, 2016](#), etc).

The study result does not verify the inverted U-shaped relations between emissions, per capita income, and food production and tend to show a flat relationship between the variables in different regression apparatus. There is a negative relationship between industry value added and food, beverages, and tobacco consumption, which confined that industrial value added largely comprises durable commodities in order to reap more economic incentives instead of agriculture intensive production. The impact of trade openness on food production index is negative that tend to show capital intensive trade instead of agriculture intensive food trade across countries. The United Nation agenda for environmental sustainability is achieved by sustainable food production, chemicals used in manufacturing value added, computer communications, combustible and renewable waste, and green ICT consumption, as these are less sensitive to carbon-fossil emissions in a panel of selected countries (see, [Jägermeyr et al., 2017](#); [Raghavan and Pargman, 2017](#), etc).

Conclusions

The era of globalization is largely provoked the need of efficient and sustainable technologies that could be used for mitigating global GHG emissions through mechanized farming, sustainable production and consumption, renewable energy mix, clean water and sanitation, climate action, and long-term global cooperation between the developed and developing countries for conservation of natural resources. These are related with United Nation sustainable development goals, which is imperative for long-term sustained growth across countries. This study focused on sustainable technologies that used in agriculture sector for improving the quality and quantity of food grains without increasing agriculture methane emissions, nitrous oxide emissions, carbon emissions, and fossil fuel energy consumption. The study considered a panel of 26 European countries for a period of 2000–2017 for policy formulation. The study used panel fixed effect model/panel random effect model in three developed models to adjust country-specific and time-invariant shocks during the study time period. The results conclude that information and communication technologies largely improve food production without deteriorating natural environment by reducing carbon-fossil emissions, while agriculture methane emissions and nitrous oxide emissions have a negative impact on food exports. Agriculture technology improves net food exports while high-technology exports increases food production on the cost of fossil fuel emissions. Thus, the policies to reduce environmental footprints in food production modeling required sustainable technologies in order to lessen the environmental cost on agriculture value added. It is evident that due to global warming and increase rice cultivation area mainly lead to increase methane emissions, while nitrous oxide emissions mainly occurred due to high use of nitrogen fertilizer use, thus, it is imperative to device sustainable agro-base policy instruments in order to mitigate climate change. would be more important to the farmers to efficiently used nitrogen as farm inputs that could reduce the risks of nitrogen oxides up to 1/3rd of the total emissions. The policies for green growth could be possible only when we achieve green revolution in agriculture sector and it is aforementioned that cleaner technologies and ICTs may play a vital role in order to improve agriculture yields. Thus, the usage of sustainable technologies in food industry is pivotal for green revolution.

Toyota Production System – Monitoring Construction Work Progress With Lean Principles

Bala SK Paladugu and David Grau, Arizona State University, Tempe, AZ, United States

Introduction

Since the 1950s the Toyota Motor Corporation has honed an advanced method of production design, control, and management referred to as the Toyota Production System (TPS). TPS is also referred to as a total, lean manufacturing, or just-in-time (JIT) production system. It adds value to the (final) customer through the utilization of cost-effective resources, elimination of waste, and continuous improvement (Brown, 2005). TPS has resulted in a quicker assembly of automobiles with high reliability and high quality-to-cost, which were attained even with the high wages of Japanese workers before the internationalization of Toyota's production (Liker, 2004). Currently, Toyota stands as the largest automotive manufacturer and the sixth largest company by revenue in the world (Fortune Global 500, 2018). The next section introduces the history behind TPS.

History

In the early 1900s, Sakichi Toyoda was an entrepreneur who designed and produced looms that were less expensive than and superior in quality to those commercially available. Later on, Sakichi leveraged steam power to streamline the weaving process through an automated loom. The weaving loom stopped when a string tore with the objective to reduce defects (Ohno, 1988; Liker, 2004). The concept of a smooth production process through autonomation (*Jidoka* in Japanese) was the essence of Sakichi's innovation and was later adopted within TPS.

In 1926, Sakichi established the Toyoda Automatic Loom Works, Ltd. In 1929, commercialization rights of the patented loom design were sold to Platt Brothers in London for £100,000 (pound value at the time). In 1930, Kiichiro Toyoda founded Toyota Motor Corporation with the profits from this transaction (Ohno, 1988; Liker, 2004). Initially, the company focused on the production of trucks (Liker, 2004).

Later, in the 1950s, Toyota's Chief Officer Eiji Toyoda – cousin of Kiichiro Toyoda – and other corporate managers traveled to the United States with the objective to learn from the direct observation of the assembly (production) lines at Ford Motor Company and General Motors Company. Despite their business success, Toyota's cohort of managers realized many inherent flaws in the assembly processes. Examples of shortcomings included uneven workflow, large inventories, wait times, disorganized workplaces, or quality issues. Upon return, Eiji Toyoda commissioned Taiichi Ohno with the design of a robust approach that could boost Toyota's production (Ohno, 1988; Liker, 2004).

Waste

Indeed, Taiichi Ohno, Toyota's chief production engineer, centered his analysis on differentiating value-added tasks and nonvalue-added tasks from a customer's perspective. Such perspective unambiguously enabled to ascertain the design aspects that added value and tracked such value through design, supply, production, and management. Ohno, while conceiving TPS, determined seven categories of waste or lack of value (*Muda*) (Ohno, 1988; Liker, 2004), which are detailed below.

- (1) *Overproduction*. Production of goods or products before they are required by downstream production (intermediate products) or customer demand (finished products).
- (2) *Waiting*. Idle time of workers, for example, waiting due to machine time, lack of parts, or tool or machine issues.
- (3) *Unnecessary handling*. Unnecessary handling of materials, parts, or goods/products. This is sometimes referred to as double- or multiple-handling. In addition to the inherent waste associated with unnecessary handling, it is also at the source of damage or quality issues and increased safety incidents.
- (4) *Overprocessing and inappropriate processing*. Overprocessing refers to processing in excess of design specifications, quality requirements, or customer expectations. Inappropriate processing reflects an inadequate use of methods, techniques, or tools and equipment. Inappropriate processing can also result from a product design with poor manufacturability and/or omissions and errors. Design omissions and errors eventually result in quality issues.
- (5) *Excessive buffers*. Excessive inventories of materials, parts, and intermediate or finished products increase production and storage costs, safety incidents, and can result in the damage of stored items.
- (6) *Unnecessary motion*. The unnecessary motion of workers or equipment/machinery. It includes unnecessary traveling, bending, reaching, or lifting. When routinely performed, unnecessary motion continuously builds waste and costs. Unnecessary motion negatively impacts workers' health and safety.

- (7) *Quality issues.* Defects or quality issues in parts or products, or the work time and equivalent costs wasted reworking defects or replacing parts or products.

Indeed, Taiichi Ohno summarized the foundation of TPS by stating that “all we are doing is taking a gander at the timeline from the minute the client gives us a request to moment that we gather money. What is more, we are decreasing the timeline by expelling nonvalue-added waste” (Ohno, 1988).

Theoretical Underpinning of Toyota Production System

In reality, in Ohno’s broadest vision, everything between a client’s command (e.g., car dealer) and the delivery of the finished product (e.g., cars) could be regarded as waste, whether it added value or not. In practice, though, nonvalue-added or actual waste was the enemy and had to be continuously eradicated. The theoretical underpinning of TPS is embedded in such a vision and rests on five main pillars. The organizational behaviors of elimination of waste (*Muda*) and continuous learning (*Kaizen*) support and feed the technical components of autonomation (*Jidoka*), JIT, and standardization (Liker, 2004). The rest of this section details the last four pillars that, when combined with waste elimination, result in the theoretical foundation of TPS. See Fig. 1.

Kaizen

Kaizen represents the organizational behavior aspect of continuous learning or improvement and sustains the work culture. Kaizen techniques aim at promoting and reinforcing continuous learning, and ultimately enhance TPS, for example contributing to waste elimination or increased efficiency. “5 Whys?” and “5S” are examples of continuous learning. “5 Whys?” is a simple technique that triggers a search for the ultimate cause of problems. Instead of asking “why?” once, it seeks a response to six questions: Who?, What?, Where?, When?, Why?, and How? (five Ws and one H) (TMMK, 2006). In addition, “5S” aims at organizing the workspace in a clean, efficient, and safe manner, with the overall goal of a productive work environment. It includes five phases (Veres et al., 2018). Sort (*Seiri*) removes what is not needed and clears the workspace. Set-in-order (*Seiton*) prepares the sequence of necessary items/tools/parts so that they can be efficiently reached and returned. Shine (*Seiso*) aims at regularly clearing equipment and workplace and including routine inspections during the clearing process. Standardize (*Seikutsu*) documents and standardizes processes and procedures in support of 5S. Finally, sustain (*Shitsuke*) aims at continuously maintaining processes and procedures, inclusive of work audits, so that these become habits within the work culture.

Just-in-Time

JIT aims at providing what is needed (i.e., materials, parts, products) in the required amount at the right location and at the right time. JIT enhances efficiency and enables quick responses to changes (TMMK, 2006). JIT reduces inventory and rework and improves quality by identifying and enabling the resolution of quality issues in real-time (Billesbach, 1987). JIT techniques include *Heijunka*, *Kanban*, or value stream mapping (VSM). *Heijunka* seeks to level production both by volume and by product type

Fig. 1 Theoretical underpinning.

(e.g., car model) against variable customer demand (TMMK, 2006). Toyota's managers envisioned that stable and lean production required an average production by volume and product type based on long-term demand forecasts as opposed to production responses to variations in short-term demand. In *Heijunka*, inventories of finished products represent buffers against sudden peaks of demand so that customer orders can be met without altering production. In addition, *Kanban* is a scheduling approach that matches inventories (e.g., parts) with actual consumption. *Kanban* is supported with signboards (such is its Japanese meaning) that inform parts that need to be made available within the production unit/facility or by outside suppliers. Such visual signs are also leveraged to control overproduction and uneven production rates (TMMK, 2006). Finally, VSM is a value improvement technique that aims at optimizing human, material, and information resources to complete business and production processes efficiently. Also, it results in the coordination of the major actors, for example, suppliers and distributors (Sundar et al., 2014).

Jidoka

Jidoka aims at the design of equipment that automatically detects production issues and stops when such issues occur. Examples of issues are equipment malfunctions, quality problems, or worker late responses (TMMK, 2006). A visual system alerts workers who assist the machine. In TPS, such type of interaction is called *autonomation*. *Autonomation* refers to “automation with a human touch” (Ohno, 1988) or intervention. Thus, workers are empowered by sensing-equipped machines to intervene and eventually stop production (e.g., with line-stop buttons), and thus prevent the flow of quality defects and production issues into downstream tasks. *Poke Yoke* and *Andon* are instances of Jidoka. *Poke Yoke* avoids mistakes by workers. Thus, a worker cannot make a specific movement or start a task on a machine if the predecessor movement or task has not been completed. Also, *Andon* refers to the notification of quality or production issues to workers and management. A visual display board with the current state of production, work instructions, issues, or progress information is an instantiation of *Andon*. *Andon* also enables a mechanism of control that triggers quick corrective actions when issues arise (TMMK, 2006).

Standardization

Standard processes and procedures enable stable, predictable, and efficient production. The organizational behavior aspect of TPS requires standardization of processes and procedures across work, supply, business, and management functions. For instance, setting the sequence of human-machine motion is an example of standardization. TPS's standardization also includes *takt time*, work sequence, and standard work-in-process inventories (TMMK, 2006). *Takt time* is the average production pace between task or workstations that matches customer demand. *Takt time* is calculated with the presumption of 100% machine production capacity (TMMK, 2006). Second, work sequence defines the detailed step-by-step order of tasks in the production line that maximizes production and minimizes waste. Finally, standard work-in-process represents the minimum inventory to maintain work. Maintaining such a minimum inventory enables workers to perform routine work continuously (TMMK, 2006).

In addition, standardization is inclusive of processes and procedures within business partners, for example, suppliers. Overall, lack of standardization precludes continuous learning.

Toyota Production System

TPS encompasses an advanced method of production design, control, and management. TPS has been observed to become “a superior way to provide better products in wider variety at lower cost, equally providing more challenging and fulfilling work for employees at every level” (Womack et al., 1990). TPS implementation and success relies on continuous learning, and knowledge consolidation and transfer within the organization and across partner organizations. There are 14 TPS principles. Each of these principles is detailed below based on the discussion by Liker (2004).

- *Principle 1. Make decisions on a long-term vision.* Maintain and communicate a vision that sets a continuous direction and prevents ever-changing responses to transient events. The long-term vision should be maintained even at the expense of lower short-term profits.
- *Principle 2. Maintain continuous flow.* Create a continuous flow of materials, parts, products, and information that brings problems to the surface.
- *Principle 3. Use “pull” production.* A task or activity signals its predecessor(s) when a feed (parts, product, and materials) is needed. Pull production results in the right quantity of products to satisfy customer orders. Pull eliminates or minimizes overproduction.
- *Principle 4. Level out workload and reduce unevenness.* Eliminate unevenness across production tasks (e.g., workstations) and schedule. Leveling out eliminates the overburdening of workers and equipment. *Takt time* is the average production pace between task or workstations that matches customer demand.
- *Principle 5. Stop to fix problems.* Design equipment that detects problems and stops when problems occur. Complementary, a visual system alerts workers that assist the machine (i.e., *autonomation*). The worker has the authority and is accountable for stopping the production/assembly line when an issue is identified.

- *Principle 6. Standardize.* Adopt stable and repeatable processes and procedures that maintain timing, predictability, and outputs. The organizational behavior aspect of continuous learning is also standardized through best practices.
- *Principle 7. Control problems visually.* Control problems with visual indicators that immediately communicate information. Visual controls prioritize the identification and/or communication of information and thus do not need to be sophisticated, even though they can be. Examples of visual controls include charts, mark tapes (e.g., on floors), arrows, colors, shapes, signboards, or displays.
- *Principle 8. Use reliable and tested technologies.* Technology is to assist employees. Avoid a technology that can conflict with the organizational culture, or that could disrupt stability, reliability, and predictability. Consider thoroughly tested technologies (i.e., proven through trials) that can serve employees and improve processes and procedures.
- *Principle 9. Grow leaders internally.* Leaders must be grown internally. Provide continuous support for exceptional employees so that they become a role model. Leaders should be embedded in the organizational behavior and understand the daily work details.
- *Principle 10. Develop exceptional people and teams.* Train individuals and teams who believe in the organizational behavior to work together and achieve outstanding results. Use cross-functional teams to enhance quality, productivity, and flow by solving difficult technical challenges. Ultimately, success relies on the team.
- *Principle 11. Respect your partners and suppliers.* Respects partners and suppliers, but at the same time challenge them to do better and help them to improve. For example, provide cross-functional teams to help and train suppliers to recognize and address problems so that they can become exceptional partners.
- *Principle 12. Go and experience by yourself.* Managers and employees alike must go to the source of a problem to observe and collect evidence as a first step to effectively solve the problem. This is sometimes referred to as *Gemba Walks*, in which employees literally walk where the problem occurs and thus enhance observation, personal interaction, and verification of issues and data. Hands-on experience is essential to resolve practical issues.
- *Principle 13. Make decisions by consensus and rapidly implement them.* Evaluate all possible solutions/alternatives before making a decision, but when a solution is devised implement it quickly and cautiously. Although looking for possible alternatives is often time-consuming, it enhances knowledge through discussions and often results in an optimum resolution.
- *Principle 14. Set a continuous learning and innovation culture.* Use relentless reflection and continuous improvement to become a learning organization. Becoming a learning organization is the final goal of TPS and feeds and supports the previous principles. A learning organization is characterized by an attitude of continuous improvement and innovation. At the same time, such continuous improvement requires reflection and analysis of previous efforts and the communication of insights, for instance through lessons learned or similar knowledge base. Continuous learning must become an intrinsic behavior within the organization.

Impact on Industry Sectors

Many companies across distinct industries have supported and improved their production capabilities with TPS principles. Instances of influence on manufacturing, medical, and construction sectors follow.

The adoption of TPS principles on distinct manufacturing industries indicates a unanimous positive impact. For example, a sensor manufacturing company integrated TPS techniques and reduced lead time by 46%, work-in-process inventory by 83%, finished inventory by 91%, overtime by 50%, and achieved 81% improvement in aggregate productivity (Liker, 2004). The implementation of TPS principles in aerospace manufacturing resulted in 20% production capacity growth (Crute *et al.*, 2003). The implementation of lean principles in tile manufacturing increased profits by 63.4 % and productivity by 47.4 %, and reduced labor cost in 11.3% and lead time by 50% (Lander and Liker, 2007).

In the health sector, the adoption of TPS principles has resulted in improved patient experience and enhanced medical performance. The design of operating rooms with TPS principles reduced patient time and thus enabled an 11% increment in surgical procedures (Castaldi *et al.*, 2016). The use of lean principles in the design of a health care facility resulted in the reduction of patient travel by 25%, staff travel by 27%, and the number of steps required to complete care procedures by 35% (Hicks *et al.*, 2015). A cardiac surgery program decreased mortality rate by 61% and major complications rate by 57% when compared against similar programs in the geographical region (Culig *et al.*, 2011). Savings of \$3,497 per each coronary artery bypass procedure were documented.

Impact on the Construction Sector: Lean Construction

Lean construction concepts and techniques were developed after TPS principles and in consideration of the unique challenges in construction, such as on-site production, outdoor conditions, industry defragmentation, or workers moving through a static product (such as a building or facility) to produce work. Construction is characterized by endemic low productivity rates when compared with the rest of nonfarming industries (Bureau of Labor Statistics, 2018). Until the recent adoption of TPS concepts, the traditional focus of management had targeted the completed product or project outcome (Grau *et al.*, 2014; Grau and Back, 2015; Grau *et al.*, 2016, 2017). Thus, management techniques had been historically developed to target the conversion of outputs from

inputs while neglecting the production process required to achieve those outputs (Howell and Ballard, 1996; Koskela, 2000). The so-called lean construction concepts and techniques emerged in the 1990s as an attempt to revamp endemic planning and production shortcomings. For example, the Last Planner System (LPS) (Ballard, 2000) has become a mainstream planning technique aiming at the improvement of workflow and minimization of variability and waste. Conceived in the early 2000s, LPS measures the number of construction tasks completed against the total number of tasks initially planned within a specified period, for example, typically a week. LPS focuses on removing constraints that can negatively affect work before supervisors commit to the work plan. With LPS, the percentage of weekly completed activities consistently exceeds 80%.

In addition, new technologies have been tested to provide visibility and inform work status in an immediate manner (Abbaszadegan and Grau, 2015). Thus, advanced sensing, computing, and information technologies have been leveraged to provide fine-grained information on construction work (e.g., steel or concrete crews) in real- or near real-time, so that such information can trigger immediate corrective actions from managers and workers when deviations occur.

Thus, the monitoring of a drywall installation activity for a new hospital facility indicated that the immediate communication and analysis of workflow triggered proactive actions that resulted in the stabilization of flow when deviations occurred (Cruz-Rios *et al.*, 2015). When meaningful differences existed between actual and planned flows, the intervention of managers resulted in reverting the actual workflow back to the planned flow rate or close to it. Deviations eventually reemerged and required additional corrective actions. In addition, pilot participants indicated the need to leverage automation during field data collection and also support information extraction and analysis with automated reasoning and alert mechanisms.

Overall, lean construction advocates envision that efficient and effective production must satisfy the three lean construction axioms of transformation-flow-value (Koskela, 2000). The transformation of outputs based on inputs reflects the traditional management focus on the finished product (Seppänen, 2009). The value aspect of production aims at optimizing the amount of value delivered to the customer. Finally, the flow aspect of production aims at the minimization of nonvalue-added steps or the simplification of production with the objective to eradicate waste. Even though far from trivial, the adoption of TPS principles within construction promises to ultimately yield production, safety, and quality records close to those in other nonfarming industries.

Conclusions

This article detailed TPS, which stands for an advanced method of production design, control, and management. TPS origin and history were explained through the entrepreneurial and innovation mindset of Kiichiro Toyoda, who founded Toyota Motor Corporation with financial resources generated through his father's loom business. Improved quality, value-added to customer, waste elimination, JIT, and continuous improvement are the main traits of TPS, which is sustained on 14 fundamental principles. Such principles can be categorized between techniques, such as pull production and work leveling, and organizational behaviors, such as continuous learning or making decisions through the lens of a sustained vision. Behavior principles result in a strong organizational culture that not only sustains the implementation of TPS but also enables its continuous refinement through data collection, analysis, and communication of lessons learned. The success of TPS is mirrored in its widespread implementation and adoption across multiple and diverse industry sectors. The unique challenges in the construction sector make lean construction – the TPS equivalent in the sector – a continuous focus for researchers and practitioners alike.

Upcycling Fresh Food Items in Retail Operations

Deishin Lee, Western University, London, ON, Canada

Mustafa H Tongarlak, Bogazici University, Bebek, Istanbul, Turkey

© 2020 Elsevier Inc. All rights reserved.

Introduction

A key challenge in retail operations is managing inventory. The retailer is constantly faced with the problem of matching demand with supply. This is particularly difficult for perishable items such as fresh produce that have limited shelf life. The value of the fresh food decreases over time, and beyond a certain point, the item can no longer be sold. To mitigate the problem of wasted food, some retailers have incorporated into their business model a practice that is common in households worldwide: Using “leftovers” or unused parts of food items to create new dishes. For example, apples close to the end of their shelf life exhibit diminished appearance, and thus could not be sold, or would need to be discounted. However, the apples could be used as an ingredient in apple pie. In fact, the use of the apples in pie may command a higher margin than selling them as fresh fruit. In this sense, the secondary use of fresh apples in pie can be considered a form of upcycling.

Reducing the Amount of Wasted Food

A critical benefit of upcycling fresh food is the reduction of wasted food. A report by the United States Department of Agriculture (USDA) estimates that 12% (4.4 billion pounds) of fresh fruit and 10% (5.2 billion pounds) of fresh vegetables were wasted at the retail level in 2010 (Buzby *et al.*, 2014). Reasons for these losses included overstocking and culling of blemished, misshapen, or wrong-sized items to accommodate esthetic criteria. At the retail level, the overall food loss (including fruits and vegetables, grain products, meat products, dairy products, etc.) was estimated to be 43 billion pounds, or 10% of the total amount.

Wasted food not only has negative economic impact, but also environmental and social impacts. The production and supply chain activities that delivered food to the retail store consumed natural and capital resources. Moreover, these activities produced by-products such as farm run-off, emissions, and road congestion, the costs of which are borne by communities. These efforts and costs borne are wasted when the food is lost. Wasted food also has detrimental social implications. The USDA estimates that 14% of US households are food insecure (USDA, 2017). That egregious amounts of food are wasted while a significant proportion of the population are vulnerable to food insecurity is particularly improvident.

The Environmental Protection Agency has endorsed a food recovery hierarchy (EPA, 2018): (1) source reduction, (2) feed hungry people, (3) feed animals, (4) industrial uses, (5) composting, (6) incineration or landfill. The process of upcycling fresh produce in retail operations is an innovative form of source reduction – the most preferred method of food recovery.

Types of Upcycling

There are two types of fresh food upcycling.

Serial Upcycling

In the “leftover” process, food is wasted when the food item is not used/consumed in a timely manner, and it degrades to the point it cannot be used in the original intended manner. For example, the selling process in a retail grocer’s fresh produce department creates leftover fresh fruits and vegetables when the produce reaches its sell-by date. However, the produce can be culled from the fresh produce department before the sell-by date and used as an ingredient to make prepared food – apples can go into apple pie, avocados into guacamole, vegetables into soup, cabbage into coleslaw, etc. (Whole Food’s Market, 2012). This is an example of *serial upcycling* – first there is an attempt to use the food item in a primary process, and if that attempt is not successful, then it is deployed in a secondary process.

Coproduct Upcycling

Another form of upcycling is when different parts of a food item are used in different products. This practice is prevalent in households and restaurants worldwide. For example, the meat of a chicken can be used for a main course dish and the bones used for chicken soup. The main course and soup use the chicken in noncompetitive ways. In fact, the more chickens that are used for the main course, the more chicken bones that are available to make soup. This form of upcycling is what we call *coproduct upcycling*. Two or more products can be produced by sharing a raw material resource. An industrial example of coproduct upcycling is the joint production of sugar and paper using sugarcane (Zhu *et al.*, 2007). Sugarcane is crushed to extract the juice, which is used to make sugar in a primary process. The dried cane residue (bagasse) is a fibrous material that is not used for sugar production but can be used in a secondary process to make

paper products. Making paper from bagasse makes productive use of a high volume by-product that would be economically and environmentally costly to dispose of, and avoids the use of virgin raw material to make paper.

Operationalizing Upcycling

Upcycling creates operational synergies and challenges. The ability to use raw material resources more productively can clearly be cost effective – both in terms of reducing raw material cost and waste disposal cost. However, upcycling can increase the complexity of an operation. There is a stream of literature that studies joint production in industrial settings [see [Lee \(2016\)](#) for a review]. We focus here on a retail grocer setting and the productive use of food waste streams in a joint production operation (upcycling).

Operationalizing Serial Upcycling

The operationalization of serial upcycling in a retail grocer setting is studied in [Lee and Tongarlak \(2017\)](#). Grocery stores face two major business risks because of the perishability of the food and the uncertainty of the demand at the time of ordering. If the grocery store carries “too little” inventory, it faces the risk of running out of stock, which results in lost sales and customer dissatisfaction. Consumers have been trained to expect constant availability of staple products. As a result, to ensure customer satisfaction, grocery stores typically carry more food than the demand forecast. This increases the risk of excess inventory (“leftover” items beyond their sell-by date), which is costly to dispose and wasteful from a natural resource perspective.

If a grocery store implements serial upcycling, then unsold fresh fruits and vegetables can be removed from the shelves before the sell-by date and used as ingredients in the prepared food department. The link between the two departments creates the synergy in serial upcycling. The waste stream from the primary process “feeds” the secondary process. From the opposite perspective, the secondary process “consumes” the waste stream of the primary process (see [Fig. 1](#)). This synergy (sometimes referred to as “by-product synergy”) has obvious cost saving benefits. The prepared food department (secondary process) utilizes the excess produce from the fresh produce department (primary process), thus avoiding both the virgin raw material cost and the waste disposal cost. By-product synergy (BPS) also provides environmental benefits in the form of waste reduction.

Some alternative ways to reduce food waste in the retail setting are stocking less, sending excess food to reclamation centers, and using pricing (discounting) to drive sales. However, stocking less leads to lower service levels and also potentially lower profit. Sending excess food to a reclamation center may not be practical for fresh produce because handling and logistics are difficult and costly. Discounting lower quality food may result in significant margin loss as the value of the item decreases considerably over time.

[Lee and Tongarlak \(2017\)](#) studied how a retail grocer can effectively implement serial upcycling, focusing on the retailer's ordering policy. The paper derives the optimal order decisions of the retailer in the “Fresh Only” and BPS settings. In the Fresh Only setting, the retailer only operates the fresh produce department (no serial upcycling). In the BPS setting, the retailer operates a prepared food department in addition to a fresh produce department and implements serial upcycling. The paper compares these two settings to determine the economic, environmental, and social implications of implementing BPS (serial upcycling).

In the Fresh Only setting, the retailer's ordering problem involves choosing the optimal quantity of the fresh produce when demand is uncertain. Suppose that the per unit cost of the fresh food item is c_1 and per unit price is r_1 . The excess fresh produce, if any, is removed from the fresh produce department and can be salvaged at a per unit value of $v_1 < c_1$. Note that the salvage value could be negative, implying disposal cost. If retailer orders “too much,” she loses her procurement cost for each unsold unit minus any salvage value ($c_1 - v_1$) – this is often referred to as the cost of overage. On the other hand, all unsatisfied demand is lost if the retailer orders “too little,” and she loses the margin ($r_1 - c_1$) for each missed opportunity to sell a unit (underage cost). The trade-off between overage cost and underage cost can be resolved optimally by a straightforward application of the Newsvendor model (see [Porteus, 2002](#)).

Fig. 1 Process flow diagram for the serial upcycling operation.

In the BPS setting, the retailer faces demand uncertainty for both the primary (fresh produce) and secondary (prepared food) products. She can jointly optimize the orders in the fresh produce and prepared food departments. Suppose that the per unit cost of other inputs in the prepared food plus the conversion cost is c_2 , the per unit price of prepared food is r_2 , and the per unit value of excess prepared food is v_2 . In the prepared food department, the optimal order quantity for new fresh produce input ingredient depends on the quantity of excess fresh produce transferred from the fresh produce department as well as the costs c_1 , v_1 , c_2 , v_2 , and the price r_2 . Lee and Tongarlak (2017) represent the optimal order-up-to level of fresh produce input ingredient for the secondary process as a function of the amount ordered in the fresh produce department, forming an extension of the Newsvendor problem. Then, the retailer's ordering problem reduces to finding the optimal orders in the fresh produce department, which is implicitly derived in the paper.

A key insight is that the optimal order quantity in the BPS setting is greater than the optimal order quantity in the Fresh Only setting. The synergy from serial upcycling drives up the amount of fresh produce ordered in the fresh produce department because the produce has the potential to be used in the prepared food department. This creates an indirect benefit from serial upcycling – the increase in the fresh produce order quantity increases the service level in fresh produce department. That is, the probability that a customer finds the fresh produce in stock (service level) is higher in the BPS setting.

The benefits of serial upcycling can only be realized if there is coordination between the two departments. In practice, coordinating separate departments to make globally optimal decisions can be organizationally more challenging for the retailer than allowing each department to optimize their own operations (resulting in lower overall profit). In particular, in the BPS setting, the primary department must overorder, thereby reducing the profit of its own operations, whereas the secondary department gains from the overordering. Therefore, even though the combined profits of the two departments increases, the primary department's performance looks worse compared with under Fresh Only.

A slight modification to BPS, called hybrid-BPS, is proposed by Lee and Tongarlak (2017) to address this organizational hurdle. In the hybrid-BPS setting, the autonomy of the departments and much of the benefit of serial upcycling synergy are preserved. The fresh produce department orders the optimal quantity presented in the Fresh Only setting. The prepared food department receives the excess inventory of the fresh produce department as in the BPS setting, and therefore chooses the order-up-to level of fresh produce input ingredient according to the optimal Fresh Only order. Compared with BPS, the expected profit is lower because the autonomous ordering of the departments results in suboptimal ordering for the retail store overall. Essentially, the fresh produce department does not “overorder” to feed the prepared food department – it simply orders what is optimal for the fresh produce department. Lower orders in the primary process also results in lower service level. However, despite the lower expected profit and service level of hybrid-BPS, the retailer may find it more desirable than optimal BPS because it is more straightforward to implement.

In addition to economic benefits to the retailer, serial upcycling can create positive environmental impact through waste reduction. Lee and Tongarlak (2017) compare the environmental impact (food waste reduction) of serial upcycling and two regulatory mechanisms used to reduce food waste: Disposal fee and donation tax credits. Disposal fees are typically charged on a per unit weight basis (e.g., landfill tip fees). A higher disposal fee reduces the salvage value of the excess inventory and thus discourages the retailer from ordering excessively in the fresh produce department. This, in turn, reduces waste, but the service level in the fresh produce department will also decrease. In contrast, serial upcycling can create more overall value because the service level in the fresh produce department increases (or at least stays the same), and food waste is reduced by diverting excess fresh produce to the prepared food department.

Giving tax credit for donation is another regulatory mechanism that diverts excess food from disposal to help those in need. The mechanism creates environmental and social value by reducing food waste and helping food insecure individuals. If the retailer donates excess fresh produce inventory, she can receive a tax credit. Lee and Tongarlak (2017) show that the waste disposal fee and tax credit are substitute mechanisms for inducing donation. The higher the disposal fee, the lower the tax credit required to induce the retailer to donate rather than to dispose. Tax credit for donation pays partially or fully for the fixed (e.g., administrative) and variable (e.g., handling and labor) costs incurred to set up an inventory donation program. Therefore, the tax credit needs to be high enough to incentivize the retailer to donate instead of disposing of excess food. If the retailer implements serial upcycling, the threshold tax credit required for donation is higher than under Fresh Only. Serial upcycling productively uses leftover fresh produce in the secondary process thereby reducing the quantity available for donation. The small amount of excess produce may not achieve the scale needed to incentivize donation. Thus, serial upcycling may have a negative impact on donation.

In summary, serial upcycling can be economically beneficial to the retailer. The optimal implementation requires coordination between the fresh produce and prepared food departments, with the fresh produce department being willing to “overorder” to supply the prepared food department. An alternate, simpler implementation allows for the two departments to operate autonomously but is not as profitable as ordering optimally. Serial upcycling helps to decrease food waste (an environmental benefit), while simultaneously increasing the service level of the fresh produce department. However, because the operation is so effective at productively using “leftover” fresh produce, there is very little excess food available for donation.

Operationalizing Coproduct Upcycling

In coproduct upcycling, the primary product uses only part of the input raw material, leaving the rest as a by-product. For example, the production of guacamole (primary product) uses the flesh of the avocado fruit, creating a by-product stream of avocado skins and pits. These by-products can then be used to produce tea (secondary product) (Beurteaux, 2018). By sharing the raw material in

Fig. 2 Process flow diagram for the coproduct upcycling operation.

a noncompetitive way, value is created by avoiding disposal cost in the primary product production, avoiding raw material cost in the secondary product production, and also potentially reducing the processing cost of the secondary product (e.g., the avocado pit has already been separated from the flesh).

Clearly, there is a quantity relationship between the amount of guacamole and the amount of avocado tea that can be produced from a given quantity of avocado. The quantity relationship is determined by the intrinsic characteristics of the avocado. However, that quantity relationship is unlikely to coincide with the relative market sizes of these products. **Fig. 2** shows the process flow diagram for the coproduct upcycling operation.

Lee (2012) studied coproduct upcycling in an industrial setting. Although the study does not focus particularly on food, the insights derived from the quantity relationship imposed by the shared material resource can shed light on joint production of food products. Suppose that for every unit of primary product that is produced, γ units of the secondary product can be produced from the unused part of the raw material. For example, suppose a pint of guacamole uses 10 avocados, and one avocado pit makes 250 ml of tea. In this case, γ is equal to 2.5 l of tea (secondary product) per pint of guacamole (primary product). However, because the primary and secondary product markets are not linked, the ratio of the optimal production quantities of the two products may not be exactly γ . Therefore, one of three policies may be optimal for a coproduct operation:

- (1) *Partial conversion*: Use only part of the unused raw material to produce the secondary product. Thus, the primary production process still disposes of some waste.
- (2) *Exactly-full conversion*: All of the unused raw material from the primary production process is used to produce the secondary product, and the secondary production process only uses the by-product stream to meet its production quantities.
- (3) *Full-plus conversion*: All of the by-product from the primary production process is used to produce the secondary product, and additionally, the secondary production process sources virgin raw material to increase production quantities beyond what is achievable with the by-product stream from the primary production process.

By joining the production of the primary and secondary processes, the cost structures of the two processes change, thereby changing the optimal production quantities. In particular, the cost of disposal is avoided in the primary process, and the cost of raw material is avoided in the secondary process.

Lee (2012) shows how the optimal operating policy depends on the relative attractiveness of the primary and secondary markets, the per unit amount of by-product generated γ , and the disposal and raw materials costs. If the primary market is relatively more attractive than the secondary market and/or the per unit amount of by-product generated γ is high, then the optimal policy is either partial conversion or exactly-full conversion. The disposal cost determines which of the two policies is optimal. For low disposal cost, partial conversion is optimal. This is intuitive because the primary market is large compared with the secondary market and disposal cost is low, so it would be optimal to only convert some of the by-product stream into the secondary product. As the disposal cost increases, it will be optimal to convert more of the by-product stream into secondary product, until a threshold level disposal cost is reached where it would be optimal to convert all of the by-product stream into secondary product.

In comparison, if the secondary market is relatively more attractive than the primary market and/or the per unit amount of by-product generated γ is low, then the optimal policy is either exactly-full or full-plus conversion. The raw material cost determines which policy is optimal. For low raw material cost, full-plus conversion is optimal – because the secondary market is robust and raw material cost is low, it's optimal to supplement the by-product stream from the primary process with virgin raw material to increase the quantity of secondary product produced. However, as raw material cost increases past a threshold amount, exactly-full conversion becomes optimal. Even though the secondary market is an attractive market, if the virgin raw material cost becomes too high, it is optimal to only make secondary product using the less expensive by-product stream from the primary process.

Another effect that coproduct upcycling has is that on average, more primary and secondary products are produced. In fact, to feed the secondary process, it may be optimal to “overproduce” the primary product (similar to the serial upcycling process). That is, the profit of the primary product could suffer from overproduction, but that is more than compensated by the increase in profit from the secondary product. Clearly, jointly producing coproducts requires making tradeoffs between the two products, but capturing the synergies can create economic, environmental, and social value. In particular, the productive use and increase in diet of fresh food can improve human health.

Future Research

The studies in this article have focused primarily on vertically integrated upcycling operations. However, as awareness of the detrimental impacts of food waste becomes more prevalent, entrepreneurs are finding innovative ways to productively use the waste streams of other organizations. A vertically disintegrated serial upcycling example is Daily Table, a nonprofit retail store that takes donations of surplus food items from a network of farmers, supermarkets, and manufacturers and either sells those items at cost or uses them to prepare “grab-n-go” meals for its customers in urban food deserts (Kowitt, 2017).

Coproduct upcycling can also be implemented in a vertically disintegrated supply chain. In fact, it is often two firms in different industries that can make use of different parts of the same raw material input. For example, the coffee cherry fruit consists of the coffee bean, surrounded by an outer husk. The coffee bean is used to make coffee, and typically, the husk has been discarded. However, Lazy Bear Tea (2018) started marketing tea drinks brewed with coffee fruit husks. Coffee farmers can now sell the bean to coffee makers and the husk to Lazy Bear Tea, thereby increasing the productive use of the coffee fruit and reducing wasted food.

When the upcycling supply chain becomes vertically disintegrated, coordination challenges surface because there is not a central planner that can facilitate the global optimization of two operations. The two processes are owned by different organizations and therefore the tradeoff between the primary and secondary processes cannot be internalized by one organization. The pricing, quantity, delivery schedule, and quality of the by-product stream must be negotiated between the two exchange parties. Given the importance of addressing the problem of wasted food, and the potential benefits to human health of increased consumption of fresh food (particularly fruits and vegetables), these supply chain challenges are important avenues for future research.

 display center 1:20–21, 1:22f
 multistoried house (rural Type I) 1:19, 1:19f
 multistoried house (rural Type II) 1:19–20, 1:20f
 precast prefabricated stilt house for ethnic community 1:20, 1:21f
 public toilet and waiting facility 1:21–22, 1:23f
 training center 1:21, 1:22f
 flooring elements 1:15
 precast ferrocement floor tiles 1:15, 1:16f
 Housing and Building Research Institute (HBRI), innovative projects by 1:22–23
 application of ferrocement technology in rural housing 1:23–24
 promoting sustainable building in Bangladesh 1:23
 standard guideline and design for rural housing in disaster prone areas of Bangladesh 1:22–23
 technical development to upgrade structural integrity of buildings 1:24
 land morphology in Bangladesh 1:1–3
 precast ferrocement irrigation drain 1:17, 1:18f
 precast ferrocement louver 1:17, 1:18f
 prevailing construction industry and its impact 1:3
 agricultural impact 1:3
 environmental impact 1:3–4
 roofing elements 1:13
 precast ferrocement corrugated sheet 1:13–14, 1:15f
 precast ferrocement folded plate 1:13, 1:15f
 precast ferrocement L-panel 1:14, 1:15f
 precast ferrocement U-channel 1:13, 1:14f
 structural elements 1:16
 precast ferrocement column/beam 1:16, 1:16f
 precast ferrocement footing 1:17, 1:18f
 precast ferrocement pile 1:16–17, 1:17f
 wall elements 1:5–6
 aerated concrete block 1:11, 1:12f
 coconut coir board 1:13, 1:14f
 compressed stabilized block with fly ash 1:10–11, 1:11f
 compressed stabilized earth block (type I) 1:9–10, 1:10f
 compressed stabilized earth block (type II) 1:10, 1:10f
 ferrocement 1:5–6, 1:5f
 interlocking compressed stabilized earth block 1:8–9, 1:9f
 interlocking compressed stabilized sand block 1:8, 1:9f
 sand-cement block (type I) 1:6–7, 1:7f
 sand-cement block (type II: 3 hole) 1:7, 1:7f
 sand-cement block (type III: 11 hole) 1:8, 1:8f
 sandwich panel 1:6, 1:6f
 thermal block (four side mortar) 1:11–13, 1:12f
 thermal block (two side mortar with key) 1:11, 1:12f
